The other important subset of C_{adm} is the set of all configurations in which the robot is grasping the part and is capable of manipulating it according to some defined criteria. Let $C_{\text{grasp}} \subseteq C_{\text{adm}}$ denote the set of *grasp configurations*. For every configuration, $(q^A, q^P) \in C_{\text{grasp}}$, the manipulator touches the part, which implies that $\mathcal{A}(q^A) \cap P(q^P) \neq \emptyset$. Just as before, penetration between the robot and part geometry is not allowed because $C_{\text{grasp}} \subseteq C_{\text{adm}}$. In general, many configurations at which $\mathcal{A}(q^A)$ contacts $P(q^P)$ will not necessarily be in C_{grasp} . The criteria for a configuration to lie in C_{grasp} depends on the particular characteristics of the manipulator, the part, and the contact surfaces between them. For example, a typical manipulator would not be able to pick up a part by making contact at only a single point. (For additional information, see Sect. 36.4 for contact state identification, Chap. 37, and grasping criteria, such as *force closure* models in Chaps. 38 and 19).

For any robot and part configuration $q = (q^A, q^P) \in C$ that we consider for manipulation planning we must always ensure that either $q \in C_{\text{stable}}$ or $q \in C_{\text{grasp}}$. We therefore define $C_{\text{free}} = C_{\text{stable}} \cup C_{\text{grasp}}$, to reflect the subset of C_{adm} that is permissible for manipulation planning. In the context of hybrid systems, this gives rise to the two distinct *modes* for manipulation planning: the *transit mode* and the *transfer mode*. Recall that in the transit mode, the manipulator is not carrying the part (i.e., only the robot moves), which requires that $q \in C_{\text{stable}}$. In the transfer mode, the manipulator carries the part (i.e., both the robot and the part move), which requires that $q \in C_{\text{grasp}}$. Based on these conditions, the only way the mode can change is if $q \in C_{\text{stable}} \cap C_{\text{grasp}}$. When the manipulator is in these configurations, it has two available actions: (1) continue to grasp and move the part, or (2) release the part in its currently stable configuration. In all other configura-

tions the mode remains unchanged. For convenience, we define $C_{\text{trans}} = C_{\text{stable}} \cap C_{\text{grasp}}$ to denote the set of *transition configurations*, which are the places in which the mode may change and the robot may grasp or release the part.

Manipulation Planning Task Definition

Finally, the basic pick-and-place manipulation planning task can now be defined. An *initial part configuration*, $q_{\text{init}}^p \in C_{\text{stable}}^p$, and a *goal part configuration*, $q_{\text{goal}}^p \in C_{\text{stable}}^p$, are specified. Recall that this high-level task specification is only defined in terms of repositioning the part, without regard to how the manipulator actually accomplishes the task. Let $C_{\text{init}} \subseteq C_{\text{free}}$ be the set of all configurations in which the part configuration is q_{init}^p

$$C_{\text{init}} = \{(q^A, q^p) \in C_{\text{free}} \mid q^p = q_{\text{init}}^p\}.$$

We define $C_{\text{goal}} \subseteq C_{\text{free}}$ similarly as the set of all configurations in which the part configuration is q_{goal}^p

$$C_{\text{goal}} = \{(q^A, q^p) \in C_{\text{free}} \mid q^p = q_{\text{goal}}^p\}.$$

If the initial and final configurations of the manipulator are specified, then let $q_{\text{init}} = (q_{\text{init}}^A, q_{\text{init}}^p) \in C_{\text{init}}$ and $q_{\text{goal}} = (q_{\text{goal}}^A, q_{\text{goal}}^p) \in C_{\text{goal}}$. The objective of the planner is to compute a path τ such that

$$\begin{aligned} \tau : [0, 1] &\mapsto C_{\text{free}}, \\ \tau(0) &= q_{\text{init}}; \tau(1) = q_{\text{goal}}. \end{aligned}$$

If the initial and final positions of the manipulator are unspecified, we implicitly define the objective of the planner as computing a path $\tau : [0, 1] \mapsto C_{\text{free}}$ such that $\tau(0) \in C_{\text{init}}$ and $\tau(1) \in C_{\text{goal}}$. In either case, a solution is an alternating sequence of transit paths and transfer paths, whose names follow from the mode. In between each transfer path, the part is placed in a stable intermediate configuration while the manipulator moves alone (transit path) in order to regrasp the part. This sequence continues until the part is ultimately placed to rest in its final goal configuration. This is depicted in Fig. 36.6.

36.3.2 Example of a Three-DOF Planar Manipulator

For manipulators with three or fewer degrees of freedom (DOF), we can construct visualizations of the C -space in order to gain an intuition of the structure. Throughout this section, we will use the example of a three-DOF serial-chain manipulator whose end-effector operates a planar workspace (\mathbb{R}^2).

Figure 36.7 shows a simple redundant robot arm originally illustrated in [36.22]. The robot has three revolute joints with parallel axes and joint limits of $-\pi, \pi$ radians, providing three degrees of freedom. Since the end-effector of the robot can only reach positions in a plane, the arm is redundant in this plane and since it has only three DOF and limits imposed on the joint angles, C can be visualized as a cube with an edge length of 2π . Generally, the C -space manifold of a manipulator with n revolute joints is homeomorphic to an n -dimensional *hypertorus* if no joint limits are present, and homeomorphic to an n -dimensional *hypercube* if joint limits are present.

Recall that obstacles in the workspace are mapped to regions in the C -space called C -obstacles (Chap. 7), which represent the set of all joint configurations of the robot that cause an intersection of the geometry of the robot and the obstacle

$$C_{\text{obs}}^A = \{(q^A, q^p) \in C \mid A(q^A) \cap \mathcal{O} \neq \emptyset\}.$$

In general, the structure of C_{obs}^A can be highly complex and involve multiple connected components of C . An example visualization of a configuration space for the planar three-DOF manipulator corresponding

Fig. 36.6 Manipulation planning involves searching for a sequence of transfer and transit paths in a set of hybrid continuous configuration spaces. In this example, transfer paths in different C -spaces arise from different ways of rigidly grasping a part

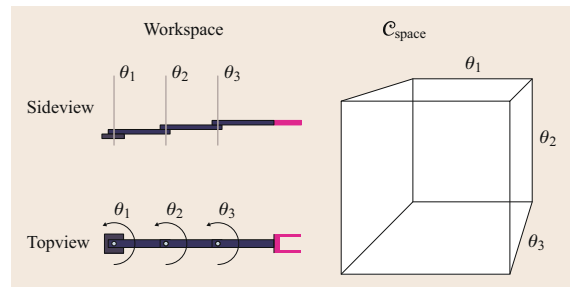

Fig. 36.7 Planar 3 DOF manipulator

to a workspace with two differently colored box-shaped obstacles is given in Fig. 36.8. The C-obstacles are illustrated using the same color as the corresponding box-shaped obstacle in the workspace. The red, green, and blue coordinate axes correspond to the three joint angles $\theta_{\{1,2,3\}}$ of the manipulator, respectively.

Self-collisions induce special C-obstacle regions that do not involve environment geometry, but only the geometric interference of the links of the robot itself. The robot shown in Fig. 36.7 is, by design, self-collision-free. Figure 36.9 shows a modified version of the manipulator, where self-collision is actually possible, and a visualization of the corresponding C-obstacles.

C-obstacles can cover large parts of the configuration space and even cause a complete disconnection between different components of C_{free} . Figure 36.10 shows how the addition of only a small post as an obstacle can cause a wide range of configurations to produce collisions and disconnect regions of C_{free} : the C-obstacle corresponding to the post forms a wall of configurations parallel to the θ_2 - θ_3 -plane. This wall represents the range of values for θ_1 for which the first link of the manipulator intersects with the post, splitting C_{free} into two disconnected components. Having disconnected components $C_1, C_2 \in C_{\text{free}}$ means that

there is no collision-free path that starts in C_1 and ends in C_2 .

36.3.3 Inverse Kinematics Considerations

The typical formulation of a path planning problem requires a goal configuration q_{goal} as input (Chap. 7). For the case of manipulation planning, this configuration is usually computed from the desired workspace pose of the end-effector by an inverse kinematics (IK) solver (Sect. 2.7). Apart from special cases, there currently exist no known analytical methods for solving the inverse kinematics of a general redundant mechanism (greater than six degrees of freedom). Iterative, numerical techniques (such as Jacobian-based methods or gradient-based optimization) are typically used to calculate solutions in this case. Note that the numerical computation of inverse kinematics solutions can suffer from poor performance or even nonconvergence, depending on the quality of the initial guess, the distribution of singularities in the C-space or a combination of these effects (Sect. 2.7).

Most IK solvers are only able to compute one configuration for a given end-effector pose. For a redundant manipulator, however, an infinite, continuous range of configurations that cause the end-effector to assume the desired pose usually exists. In the context of path planning, this means that the IK solver will select one out of an infinite number of configurations as q_{goal} . Note that in some cases, the selected q_{goal} might not be collision-free, i. e., it is not part of C_{free} . Such a configuration cannot be used as a goal for computing a global reaching strategy because no solution exists for the corresponding path planning query in the classical sense (Chap. 7).

Another possibility is that the selected q_{goal} might be disconnected from q_{init} . In this case, q_{goal} is unsuitable for planning despite the fact that it is a member of C_{free} , because it is in a component of C_{free} that is disconnected from the component in which q_{init} lies. Consider the planar manipulator shown in Fig. 36.7.

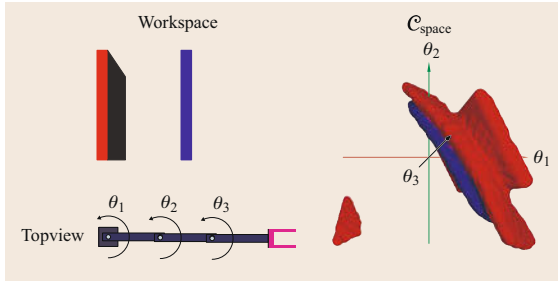

Fig. 36.8 Planar 3 DOF manipulator in a workspace with box-shaped obstacles and associated configuration space obstacles

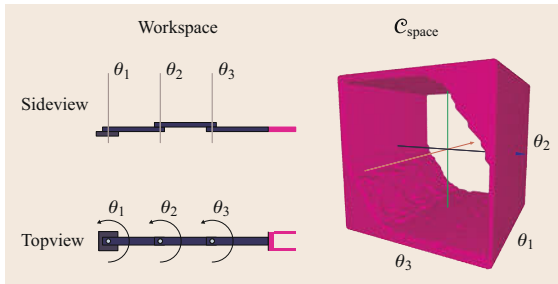

Fig. 36.9 Non-planar 3 DOF manipulator and corresponding self-collision C-obstacle

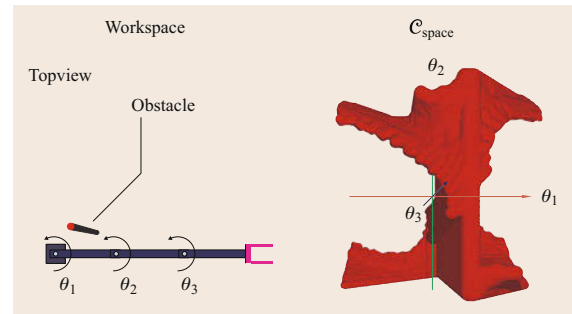

Fig. 36.10 Workspace mapping to a configuration space with topologically disconnected components

Figure 36.11 shows two possible solutions for a certain end-effector pose. The corresponding configurations $q_a = (0, \pi/2, 0)$ and $q_b = (\pi/2, -\pi/2, \pi/2)$ are marked by green spheres in the C -space visualization. In this case, the IK solver might select one of the two solutions as q_{goal} . If the same obstacle as in Fig. 36.10 is added to the workspace, the two solutions will lie in disconnected components of C_{free} , as shown in Fig. 36.12.

Let $q_{\text{init}} = (0, 0, 0)$ be the zero configuration, marked by the point of intersection of the C -space axes in Fig. 36.12. Let the component of C_{free} in which it lies be denoted by C_1 and the other component by C_2 . Since $q_b \in C_2$ and $C_1 \cap C_2 = \emptyset$, no solution for the planning problem can exist if the IK solver selects q_b as q_{goal} . This means that every planning attempt with this q_{goal} will invariably fail.

Since computing a complete representation of the connectivity of C is a problem of similar complexity to path planning itself, it is virtually impossible to detect a disconnection between q_{goal} and q_{init} before the planning attempt has failed.

Fig. 36.11a–c Two inverse kinematics solutions for the same end-effector pose of a planar 3 DOF arm; (a) solution 1, (b) solution 2, (c) solution shown in C space

Fig. 36.12a–c Two inverse kinematics solutions lying in disconnected components of C_{free} due to a small obstacle in the workspace; (a) solution 1, (b) solution 2, (c) the two solutions shown in C space, which are in disconnected components

Recall that the workspace goal for a classical manipulation planning problem is defined by a desired end-effector pose computed using inverse kinematics. Note however, that the purpose of a manipulation task may not require moving the end-effector to that particular location, but rather moving it to *any* feasible location which enables the desired manipulation task to be solved. Thus, it becomes important to devise computational methods and control schemes that are focused around the task, and allow some flexibility and freedom with regards to the end-effector pose and manipulator configuration. This is one of the motivations and advantages of task space or operational space control techniques (Sect. 8.2).

As an example, consider the task of grasping a cylindrical part with the planar three-DOF manipulator. Figure 36.11 shows two possible solution configurations yielding the same end-effector pose. The addition of obstacles to this workspace may cause one of the configurations to become disconnected from the zero configuration. These two configurations, however, may not be the only valid configurations that allow the manipulator to grasp the cylindrical part. Figure 36.13a shows several other configurations that allow the manipulator to grasp the part. By interpolating between these, an infinite number of different workspace poses that provide solutions to the grasping problem is generated. The inverse kinematics solutions associated with these workspace poses are contained in the continuous subset $C_{\text{goal}} \subseteq C$, as shown in Fig. 36.13b, which represents the actual solution space to the planning problem for this reaching task.

Adding the obstacle from Fig. 36.10 to the workspace of this manipulation task produces the configuration space depicted in Fig. 36.14. Note that the C -obstacle corresponding to collisions between the manipulator and the cylinder itself has been disregarded in this visualization for clarity. Approximately half of the

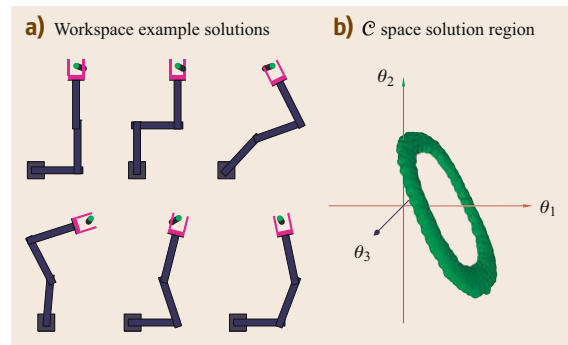

Fig. 36.13 (a) Multiple arm configurations that allow the manipulator to grasp the cylinder and (b) C -space visualization of the set of solution configurations

possible solutions are disconnected from the zero configuration and a quarter are in collision, which leaves only one quarter as reachable and therefore suitable candidates for q_{goal} in a classical planning query.

36.3.4 Continuum Manipulation

As introduced in Chap. 20, a manipulator with far more degrees of freedom than that of an object to be manipulated is a hyperredundant manipulator. Hyperredundant manipulators can be further classified into vertebrate-like rigid-link manipulators, such as snakes, and invertebrate-like continuum manipulators, such as octopus arms or elephant trunks. Many vertebrate-like manipulators inherit the kinematics of articulated arms, and like the articulated arms, they are often used as carriers

Fig. 36.14 Two views of the set of goal configurations (green) for grasping a cylindrical part in a disconnected C-space

Fig. 36.15 Different configurations of the OctArm manipulator

of the actual manipulators: hands or grippers, such as in surgical applications.

Continuum manipulators [36.23], on the other hand, consist of deformable sections and are often used for whole-arm manipulation without a divide between the *arm* and *hand/gripper*, taking advantage of their compliance and flexibility. They can be viewed as the extreme case of hyperredundancy but are fundamentally different from articulated arms. A *grasping* configuration for a continuum manipulator affects the whole arm as it wraps around an object. The smooth and compliant nature of a continuum manipulator allows it to gently interact with the object by adapting its shape to the object it wraps. The OctArm [36.24], with multiple constant-curvature sections, is representative of the general class of continuum manipulators.

Although each section i of a continuum manipulator is deformable, and thus has infinite degrees of freedom theoretically, it often has three controllable degrees of freedom, which describes the configuration of the section as a truncated torus when undeformed or a cylinder if the curvature is zero. length s_i , curvature κ_i , and the orientation angle ϕ_i between section $i - 1$ and section i . By changing those three variables for each section, the configuration of the whole manipulator can be changed. Figure 36.15 shows different configurations of a three-section OctArm.

Planning for continuum, whole-arm manipulation is significantly different from manipulation and grasping planning for conventional articulated arms with hands/grippers. Here the inverse kinematics problem is to find end positions of each section for the manipulator, given the configuration variables of the section [36.25]. However, planning motion for whole-arm manipulation has to consider directly a mixture of configuration variables and Cartesian-space variables (i. e., the end position of each section), because the shapes and grasping capabilities of the end-effector (which can be viewed as the portion of the continuum manipulator contacting the target object) depend on both.

Given a target object, its location and size decide if there exists a configuration that a continuum manipulator can wrap around the object to grasp it. If wrapping around the object along one circle is sufficient, that bounding circle of the object centered at position c with radius r_c determines the k ($k \leq n$) sections that are needed to wrap it, starting from the tip n -th section backward. The poses of the remaining $n - k$ sections must satisfy the intersection constraints to form feasible whole-arm configurations for grasping [36.26]. A feasible grasping configuration can also be determined heuristically as an integral part of collision-free motion planning [36.27]. Multiple grasping solutions provide flexibility to avoid obstacles (VIDEO 357).

A more practical approach [36.28] is to first make a contact between the manipulator and the target object at the m -th section ($m < n$), and then generate wrapping configurations for the m to n sections of the manipulator one by one without overlap to form a tight, spiral wrap (i. e., along multiple object bounding circles). In a cluttered environment, progressive wrapping of an object can be achieved through moving all arm sections together led by the tip of the arm to surround the object [36.29], which requires minimum free space for the arm to maneuver. Those approaches can generate a better force-closure grasp and facilitate sensing-based manipulation based on contact detection.

Finally, strategies for planning continuum manipulation could also benefit whole-arm manipulation with

vertebrate-like hyperredundant manipulators in that the planned spatial curves for poses of a continuum manipulator could be used as desired shapes for a hyperredundant manipulator, such as a snake robot, to fit its joint configurations. Indeed, curve design and fitting for hyperredundant manipulators has long been introduced for planning manipulator poses [36.30].

In this section, we have covered the basics of manipulation planning, developed a mathematical formulation for the kinds of search spaces that arise, and discussed some of the important geometric and topological considerations, as well as different types of manipulators and manipulation. Section 36.6 provides an overview of additional topics and extensions with pointers to further reading.

36.4 Assembly Motion

Assembly or an *assembly task* defines the process of putting together manufactured parts to make a complete product, such as a machine. It is a major operation in the manufacturing process of any product. Assembly automation with robots aims to reduce cost and increase the quality and efficiency of the operation. In environments hazardous to humans, such as in space, having robots perform assembly tasks could save human lives. Assembly has long been not only an important but also one of the most challenging applications for robotics. There are many significant research issues related to the broad scope of assembly automation, from design for assembly [36.31] to tolerance analysis [36.32], assembly sequence planning [36.33], fixture design [36.34], etc. This section is only focused on the issue of robotic motion for assembly.

The concerned *assembly motion* is that of a robot manipulator holding a part and moving it to reach a certain *assembled state*, i. e., a required spatial arrangement or contact against another part. The main difficulty of assembly motion is due to the requirement for high precision or low tolerance between the parts in an assembled state. As a result, the assembly motion has to overcome uncertainty to be successful. *Compliant motion* is defined as motion constrained by the contact between the held part and another part in the environment. As it reduces uncertainty through reducing the degrees of freedom of the held part, compliant motion is desirable in assembly.

Consider the peg-in-hole insertion example introduced earlier (Fig. 36.2). If the clearance between the peg and the hole is very small, the effect of uncertainty will most likely cause a downward insertion motion of the peg to fail, i. e., the peg ends up colliding with the entrance of the hole in some way without reach-

ing the desired assembled state. Therefore, a successful assembly motion has to move the peg out of such an unintended contact situation and lead it to reach the desired assembled state eventually. To make this transition, compliant motion is preferred. Often a sequence of contact transitions via compliant motion is necessary before the desired assembled state can be reached. Figure 36.16 shows a typical sequence of contact transitions for the peg-in-hole task.

Assembly motion strategies that incorporate compliant motion can be broadly classified into two groups: *passive compliance* and *active compliant motion*, and both groups of strategies require certain informa-

Fig. 36.16 A sequence of contact transitions for the peg-in-hole insertion task

tion characterizing *topological contact states* between parts.

36.4.1 Topological Contact States

When a part A contacts a part B, the configuration of A (or B) is a *contact configuration*. Often a set of contact configurations share the same high-level contact characteristics. For example, *a cup is on the table* is a high-level description shared by all the contact configurations of the cup when its bottom are on the table. Such a description is often what really matters in assembly motion as it characterizes a spatial arrangement that could be either an assembled state or just a *contact state* between a part and another part.

For contacting polyhedral objects, it is common to describe a *contact state* topologically as a set of *primitive contacts*, each of which is defined by a pair of contacting surface elements in terms of faces, edges, and vertices. Different contact state representations essentially differ only in how primitive contacts are defined. One common representation [36.35] defines primitive contacts as point contacts in terms of vertex–edge contacts for two-dimensional (2-D) polygons, and vertex–face and edge–edge contacts for three-dimensional (3-D) polyhedra. Another representation [36.36] defines a primitive contact as between a pair of *topological surface elements* (i.e., faces, edges, and vertices). Here a contact primitive can characterize a contact region that is either a point, a line segment, or a planar face, unlike the point-contact notion. From the viewpoint of contact identification via sensing, however, both representations can result in states that are different by definition but indistinguishable in identification due to uncertainties. Figure 36.17 shows such an example.

The notion of a *principal contact* [36.37,38] presents a high-level primitive contact that is more robust to recognition. A *principal contact* (PC) denotes a contact between a pair of topological surface elements that are not boundary elements of other contacting topological surface elements. The boundary elements of a face are the edges and vertices bounding it, and the boundary elements of an edge are the vertices bounding it. Different PCs between two objects correspond to different degrees of freedom of the objects, which often also correspond to significant differences in the contact forces and moments. As shown in Fig. 36.17, the indistinguishable states in terms of the other contact primitives are grouped as a single contact state in terms of PCs. Thus, there are also fewer contact states in terms of PCs, leading to a more concise characterization of contact states. In fact, every contact state between two convex polyhedral objects is described by a single PC.

36.4.2 Passive Compliance

Passive compliance refers to strategies that incorporate compliant motion for error correction during the assembly motion without requiring active and explicit recognition and reasoning of contact states between parts.

Remote Center Compliance

In the 1970s, a *remote center compliance* (RCC) device was developed to assist high-precision peg-in-hole insertion [36.39–41]. The RCC is a mechanical spring structure used as a tool attached to the end-effector of a robot manipulator to hold a round peg when it is inserted into a round hole. The RCC is designed to have high stiffness along the direction of insertion but high lateral and angular compliances K_x and K_θ , and it projects the center of compliance near the tip of the peg (hence the name remote center compliance) to overcome small lateral and angular errors in the peg's position and orientation in response to the contact forces applied to the peg by the hole during insertion (Fig. 36.18). The large lateral and angular compliance of the RCC also helps to avoid *wedging* and *jamming*, conditions that cause the peg to stick in two-point contacts due to contact forces in direct opposition (wedging) or ill-proportioned contact forces/moments (jamming). Because the RCC is low cost and reliable for fast insertions, it has long seen successful industrial applications.

However, the RCC has limitations. It only applies to round peg-in-hole insertions, and a particular RCC works better for a peg and hole of a particular size. Attempts have been made to expand the applicability of the RCC. Some attempts try to make certain param-

Fig. 36.17a–c Indistinguishable contact states due to positional uncertainty of the top part; (a) two objects, (b) state 1, (c) state 2

eters of an **RCC** adjustable to achieve variable compliance or projection (i.e., the position of the remote center) [36.42–44]. A spatial **RCC** (**SRCC**) [36.45] was proposed to achieve square-peg-in-hole insertions. A notable difference with this extension is the combinatorial explosion of the number of possible contact states, given the range of the position and orientation uncertainty of the held part that have to be considered in the design of the device. Unlike the case of the round peg and hole, which is essentially a 2-D problem with a handful of different contact states, there are hundreds of possible different contact states between a square peg and a square hole. From each of these possible contact states, a motion leading the held part to the goal assembled state has to be realized by the device. This makes it difficult to design an **RCC** device that works for parts of more general and complex shapes with more possible contact states between them. This is a major limiting factor that prevent more extensions of the **RCC** to assembly of different parts.

Admittance Matrix

As an alternative method to the **RCC**, a particular form of manipulator force control, damping control, was proposed to achieve compliant motion of the held part by the manipulator and to correct small location errors of the held part during assembly. This approach eliminates the need to build a mechanical device like an **RCC** to achieve error correction. Among the force control laws [36.46], damping control is a common strategy, where a commanded velocity of the held part is modified based on the sensed force caused by contact between the held part and the environment. The resulted actual velocity leads to reduction and hopefully eventual correction of small position or orientation errors of the held part. Let \mathbf{v} be a six-dimensional (6-D) vector representing the actual translational and angu-

lar velocity of the held part, \mathbf{v}_0 be the six-dimensional commanded velocity, and \mathbf{f} be a six-dimensional vector representing the sensed force and moment. A linear damping control law is described as

$$\mathbf{v} = \mathbf{v}_0 + \mathbf{A}\mathbf{f},$$

where \mathbf{A} is a 6×6 matrix, called an *admittance matrix* or accommodation matrix.

The effectiveness of such a damping control law depends on the existence and finding of a proper admittance matrix \mathbf{A} . There is considerable research on the design of a single \mathbf{A} that can make an assembly operation successful regardless of what contact states the held peg may encounter in the process [36.47–51]. This is aimed at cases where a single commanded velocity would be sufficient to achieve an assembly operation when there were no uncertainty or error, such as certain peg-in-hole insertion operations. One main approach to design \mathbf{A} is based on explicit kinematic and static analysis of contact conditions under all possible contact states and mating requirements, which result in a set of linear inequalities as constraints on \mathbf{A} . Learning is also used [36.50] to obtain an \mathbf{A} that minimizes the force \mathbf{f} without causing instability. Another approach [36.51] applies perturbations to the end-effector during insertion in order to obtain richer force information.

Learning Control for Assembly

Another category of approaches is to learn proper control for a particular assembly operation through stochastic or neural-network-based methods [36.52–56]. The essence of most of these approaches is to learn to map a reaction force upon the held object caused by contact to the next commanded velocity in order to reduce errors and to achieve an assembly operation successfully. A more recent approach [36.56] maps fused sensory data of pose and vision obtained during human demonstration of assembly tasks to compliant motion signals for successful assembly.

A different approach observes assembly tasks performed by human operators through vision [36.57] or in a virtual environment [36.58, 59] and generates a motion strategy necessary for the success of the task that consists of a sequence of recognized contact state transitions and associated motion parameters.

As a sequence of commanded velocities can be generated, unlike **RCC** or strategies based on a single admittance matrix described above, can be applied to cases with large uncertainties. However, the learned controllers are task dependent.

More recently, an approach combining vision and force sensing for assembly was introduced [36.60] based on measuring the deformation of parts through vision to adjust desired forces for mating and achieve

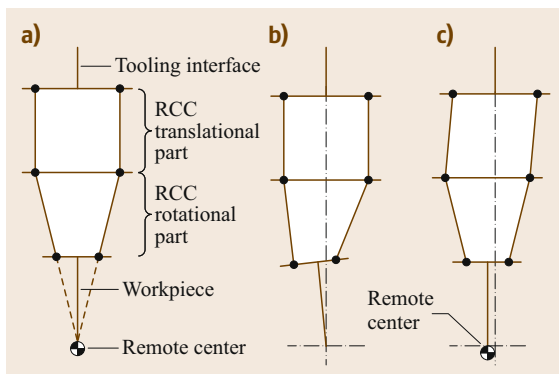

Fig. 36.18 (a) Planar representation of **RCC**. (b) Rotational part of **RCC** allowing workpiece to rotate. (c) Translational part of **RCC** allowing workpiece to translate

force control through force sensing and an impedance controller. The approach was applied to the task of mating two power connectors. The effect was similar to having an **RCC** device on the end-effector.

All of the above assembly motion strategies do not require explicit recognition of contact states during their execution.

36.4.3 Active Compliant Motion

Active compliant motion is characterized by error correction based on online identification or recognition of contact states in addition to feedback of contact forces. The capability for active compliant motion allows a robot the flexibility to deal with a much broader range of assembly tasks with large uncertainties and tasks beyond assembly where compliance is required. An active compliant motion system generally requires the following components: a planner to plan compliant motion commands, an identifier to recognize contact states, state transitions, and other state information during task operation, and a controller to execute compliant motion plans based on both low-level feedback provided by sensors and high-level feedback provided by the identifier. Research on each component is described below.

Fine Motion Planning

Fine motion planning refers to planning fine-scale motions to make an assembly task successful in spite of significant uncertainties. A general approach was proposed [36.61] based on the concept of preimages in configuration space (C-space) [36.35] to devise motion strategies that would not fail in the presence of uncertainties. Given a goal state of the held part defined by a region of goal configurations, a *preimage* of the goal state encodes those configurations from which a commanded velocity will guarantee that the held part reaches the goal state recognizably in spite of location and velocity uncertainties (Fig. 36.19).

Given the initial location of the held part and the goal state, the preimage approach generates a motion

plan in backward chaining by finding the preimage of the goal state associated with a commanded velocity and then the preimage of the preimage, and so on, until a preimage that includes the initial configuration of the held part is found. Figure 36.20 shows an example.

The sequence of commanded velocities associated with the sequence of preimages (starting from the initial preimage that includes the initial location) forms the motion plan that guarantees the success of the task. Starting from the initial preimage, each subsequent preimage in the sequence can be viewed as a subgoal state. In this approach, compliant motions are preferred wherever possible because they typically produce larger preimages [36.61] than pure positioning motions, and subgoal states are often contact states. The approach was further extended [36.62] to include modeling uncertainties of objects.

However, the computability of the approach is a major problem. The requirement of both goal reachability and recognizability under sensing uncertainties, which are intertwined issues, complicates the computation of preimages. It has been shown [36.63] that the time complexity of generating a plan can be double exponential in nmr , where n is the number of plan steps, m is the environment complexity (of the physical space), and r is the dimension of the configuration space. By separating reachability and recognizability and restricting the recognizability power of the original preimage model, computability was improved [36.64, 65].

As an alternative, a two-phase approach is to simplify the fine motion planning into (1) global and offline nominal path planning assuming no uncertainty and (2) local and online replanning to deal with unintended contacts due to uncertainties. Different variations of the two-phase approach have been proposed [36.66–72]. The success of such an approach depends on successful online identification of contact states (Sect. 36.4.3).

Several researchers also studied the representation and propagation of uncertainties and constraints that have to be satisfied for the success of a task [36.73–77].

Fig. 36.19a,b Location and velocity uncertainties (in the C-space). **(a)** The actual configuration of a part could be inside an uncertainty ball centered at an observed configuration. **(b)** The actual velocity of a part could be inside an uncertainty cone of a commanded velocity

Compliant Motion Planning

Compliant motion planning focuses on planning motions of objects always in contact. *Hopcroft and Wilfong* [36.78] proved that, if two arbitrary objects in contact can be moved to another configuration where they are also in contact, then there is always a path of contact configurations (on the boundary of configuration space obstacles, or *C*-obstacles) connecting the first and second contact configurations. Therefore, not only is compliant motion desirable in many cases, but it is always possible given initial and goal contact configurations.

Because compliant motion occurs on the boundary of *C*-obstacles, planning compliant motion poses special challenges not present in collision-free motion planning: it requires the exact information of contact configurations on the boundary of *C*-obstacles. Unfortunately computing *C*-obstacles exactly remains a formidable task to date. While there are exact descriptions of *C*-obstacles for polygons [36.79, 80], which are three dimensional, there are only approximations of *C*-obstacles for polyhedra [36.81, 82], which are six dimensional. If m and n indicate the complexity of two polyhedral objects in contact, the complexity of the corresponding *C*-obstacle is $\Theta(m^6 n^6)$ [36.83].

Researchers have focused on either reducing the dimensionality and scope of the problem or getting around the problem of computing *C*-obstacles altogether. Some researchers have studied compliant motion planning on *C*-obstacles of reduced dimensions [36.72, 84, 85]. It is more popular to plan compliant motions based on a predetermined graph of topological contact states to avoid the problem of computing *C*-obstacles [36.86–89]. In particular, one approach [36.87, 88] models an assembly task of polygonal parts as a discrete event system using Petri nets. However, contact states and transitions are often generated manually, which is awfully tedious for even assembly tasks of simple geometry [36.45] and is practically infeasible for complex tasks due to the huge number of different contact states.

Therefore, automatic generation of a contact state graph is desirable and even necessary. A method was first developed to enumerate all possible contact states and their connections between two convex polyhedral objects [36.90]. Recall that a contact state between two convex polyhedra can be described by a single principal contact (Sect. 36.4.1), and any principal contact between two topological surface elements of two convex polyhedra describes a geometrically valid contact state. These are nice properties and greatly simplify the problem of contact state graph generation. In general, however, to construct a contact state graph between two objects automatically requires the handling of two

rather difficult issues:

1. How to generate *valid* contact states, i. e., how to tell if a set of principal contacts corresponds to a geometrically valid contact state, given the geometries of objects, and
2. How to link one valid contact state to another in the graph, i. e., how to find the neighboring (or adjacency) relations among the regions of contact configurations belonging to different contact states in the contact configuration space.

A general and efficient divide-and-merge approach was introduced [36.38] for automatically generating a contact state graph between two arbitrary polyhedra. Each node in the graph denotes a contact state, described by a topological *contact formation* (CF) [36.37] as a set of principal contacts and a configuration satisfying the CF. Each edge connects the nodes of two neighboring contact states. Figure 36.21 shows an example contact state graph between two planar parts.

The approach handled the above two issues simultaneously by directly exploiting both topological and geometrical knowledge of contacts in the *physical space* of objects and by dividing the problem into simpler subproblems of generating and merging special subgraphs. Specifically, the approach takes advantage of the fact that a contact state graph can be divided into special subgraphs called the *goal-contact relaxation* (GCR) graphs, where each GCR graph is defined by a locally most constrained valid contact state, called the seed, and its less-constrained neighboring valid contact states, which is easier to generate because of several properties. The main properties include:

- Given a valid contact state CS_i , all of its less constrained neighboring contact states can be hy-

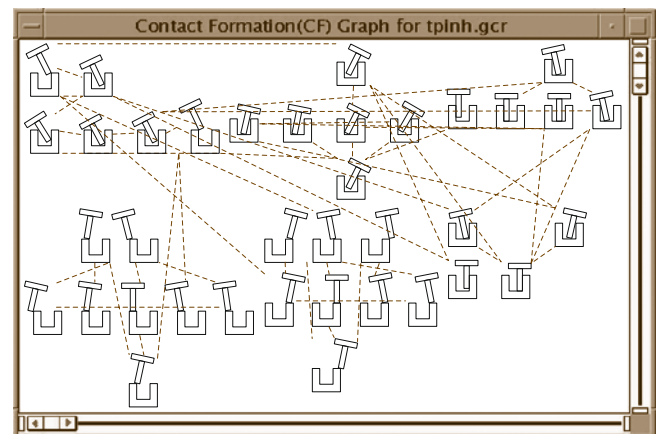

Fig. 36.21 A contact state graph between two planar parts

pothesized topologically from the principal contacts in CS_i .

- A hypothesized less constrained neighboring contact state CS_j is valid, if and only if there exists a compliant motion to relax certain constraints of CS_i to obtain CS_j which does not result in any other contact state, called neighboring relaxation.
- Neighboring relaxation can often be achieved by instantaneous compliant motion.

With this approach, a contact state graph of several hundreds or thousands of nodes and links can be generated in a few seconds.

With a contact state graph, the problem of compliant motion planning can be decomposed into two simpler subproblems at two levels: (1) high level: graph search for state transitions from one node to another in a contact state graph, and (2) low level: contact motion planning within the set of contact configurations constrained by the *same* contact state (and the same contact formation), called *CF-compliant motion planning*. A general contact motion plan crossing several contact states can be considered as consisting of segments of CF-compliant motions in different contact states. One approach plans [36.91] CF-compliant motions based on random sampling of CF-compliant configurations and extending the probabilistic roadmap motion planning technique [36.92].

Contact State Identification

Successful execution of a fine-motion or compliant motion plan depends on correct online identification of contact states during execution. Contact state identification uses both model information of contact states (including topological, geometrical and physical information) and sensory information of location and force/torque of the end-effector. The presence of sensing uncertainties make the identification problem non-trivial. Approaches for contact state identification are different in ways of dealing with uncertainties.

One class of approaches obtain the mapping between sensory data (in the presence of sensing uncertainties) and corresponding contact states through learning. Models for learning include hidden Markov models [36.93, 94], thresholds [36.95, 96], neural network structures, and fuzzy classifiers [36.97–101]. Training data are obtained either in an unsupervised way or by human task demonstration. Such approaches are task dependent: a new task or environment requires new training.

Another class of approaches are based on analytical models for contact states. A common strategy is to pre-determine the set of configurations, constraints on configurations, or the set of forces/torques or force/torque

constraints that are possible for each contact state and match such information against the sensed data to identify contact states online. Some approaches do not consider the effect of uncertainties [36.102, 103], while others consider uncertainties modeled either by uncertainty bounds or by probability distributions [36.36, 89, 104–108]. An alternative strategy is based on checking the distance between contacting elements in Cartesian space: either by growing the objects with pose uncertainty and intersecting the obtained regions [36.109], or by combining the distance between the objects with several other factors such as the instantaneous approach direction [36.110].

In terms of how sensory data are used, some identification schemes are rather static because they do not consider the prior motion and state identifications before the current contact state is reached, while others use prior history or even use new motion or *active sensing* to help current identification. The latter include approaches that perform simultaneous contact state identification and parameter estimation. In such approaches, an analytical contact state model is expressed as a function of uncertain parameters, such as the pose or dimension of an object in contact. At each contact state, some of the uncertain parameters can be observed or estimated with reduced uncertainty. For example, if the held object is at a face–face contact with another object, parameters describing the normals of the contacting faces can be estimated with the help of force/torque sensing. During a task execution (i.e., the execution of a motion plan), the uncertain parameters are estimated along with the identification of contact states with increasing accuracy, which in turn makes the subsequent contact state identifications more accurate. This also improves force control and contact state transition monitoring. The increased performance, however, comes at a higher computational cost.

Simultaneous contact state identification and parameter estimation is most often done by ruling out contact state models that are inconsistent with sensed data or parameter estimation results [36.111–117]. One notable exception [36.118] performs a truly simultaneous estimation by describing the system as a hybrid joint probability distribution of contact states and parameters.

Active sensing is about deliberate use of applied force/torque or motion to better aid contact state identification and parameter estimation. Earlier research focused on simple force strategy [36.119] or movability tests [36.36, 110]. More recently, methods were introduced [36.120] to design sequences of contact state transitions and compliant motion strategies that were optimized for active sensing to determine all uncertain

geometric parameters while achieving certain goal contact state.

From a different perspective, an approach was introduced to analyze contact state distinguishability and unknown/uncertain parameter identifiability [36.121] during the design phase of a contact state identifier or parameter estimator.

36.4.4 Compliant Motion Under Manipulator Constraints

A general compliant motion plan (as the output of a compliant motion or fine motion planner) usually consists of a sequence of contact states, and within each contact state, a path of contact configurations compliant to the contact state and leads to the next contact state in the sequence. Each contact configuration is described in terms of the parts in contact. However, it takes a robot manipulator to move one part against the others, especially in assembly tasks. Therefore, whether a contact state can be formed and whether a compliant motion and a contact state transition is possible is subject to the constraints of the manipulator.

Feasibility of Contact States and Compliant Motions

A contact state graph should be re-visited by considering manipulator constraints [36.122]. Contact configurations compliant to a given contact state are sampled and applied inverse kinematics to check if there is a feasible manipulator joint-space configuration to realize the contact state. If no feasible manipulator configuration can be found after a number of samples are considered, the contact state is considered at least very difficult to reach, and is discarded from the graph as an infeasible state.

Given two feasible adjacent contact states, a compliant motion for their transition should also be checked for feasibility under manipulator constraints. The main issue here is how to deal with possible singularities along the compliant path (of contact configurations). Certain singularities can be escaped if the manipulator is redundant (i.e., with more than six degrees of freedom) [36.123]. With inescapable singularities, the compliant path of the moved object is not feasible and has to be either altered to avoid singularity [36.124] or abandoned. However, an altered path may no longer be compliant to the desired contact states. In practice, it is preferred to check the feasibility of a compliant path starting from the goal contact state of an

assembly task backward to make sure that the feasible portion leading to the goal as well as the feasible contact states encountered are discovered and preserved [36.125].

Execution of Feasible Compliant Motion Plans

Depending on whether the manipulator is equipped with a force/torque sensor or not, different control schemes can be considered for executing a compliant motion plan that includes multiple contact state transitions ( VIDEO 356).

If the manipulator has a force/torque sensor, a hybrid position/force controller can be used. It requires a specification that separates dimensions of force control from those of position/velocity control. Such specifications not only have to vary for different contact states but may have to vary from one contact configuration to another within the same contact state, i.e., a control specification is a function of time or configuration along a compliant trajectory in general. Moreover, it is far from trivial to make control specifications for complex contact states involving multiple principal contacts [36.126].

An approach was introduced [36.127] to convert automatically a compliant path of contact configurations across a sequence of contact states into wrench, twist, and position control signals $w(t)$, $t(t)$, and $p(t)$ for a hybrid controller to execute the plan. The approach was experimentally verified successfully.

More recently, an approach was introduced [36.128] to achieve force control by estimating contact force/torque from the joint torques without using a force sensor for the end-effector force/torque or torque sensors for individual joints. By reducing the integral gain of the joint PID (proportional–integral–derivative) controller, the approach acts like a high-pass filter to detect sharp force/torque changes more effectively, which often indicates contact state changes. Combining such detection with position control, the approach was able to execute an assembly motion plan successfully, even though compliant motion could not always be maintained with position control.

Other approaches to realize force control without a force sensor requires the dynamic model of the manipulator [36.128–130].

However, there is not yet a full integration of planning, online contact state identification, online replanning (to deal with contact states that are off the preplanned path due to uncertainty), and compliant motion control.

36.5 Unifying Feedback Control and Planning

In previous sections we discussed task-level control methods and planning algorithms. Both task-level control and planning methods are able to address specific constraints imposed on robot motion in the context of manipulation tasks. However, as illustrated in Fig. 36.3, neither of these categories of methods is able to address all constraints completely. Control remains susceptible to local minima and thus cannot guarantee that a particular motion will lead to the desired result. Planning methods, on the other hand, overcome the problem of local minima by projecting possible motions into the future to predict if a sequence of motion will lead to success. Given certain assumptions, the resulting plan can be guaranteed to succeed. However, the computations associated with this process are generally too computationally complex to satisfy the feedback requirements of manipulation tasks. Unfortunately, this means that control and motion planning by themselves are unable to address the problem of moving robots for general manipulations tasks.

In this final section of this chapter, we will review efforts to combine the advantages of control methods and planning methods into a single approach to determine the motion of a robot. These efforts aim to create methods that avoid the susceptibility to local minima while satisfying the feedback requirements. Early attempts of integrating planning and control occurred in the early 1990s. Not all of these efforts are specifically directed at manipulation but many contain insights relevant to the topic. In this section, we will review these efforts and also discuss some of the more recent research efforts aimed at unifying motion planning and feedback control.

Motion planning (Chap. 7) and motion control (Chap. 8) have traditionally been regarded as two distinct areas of research. However, these areas have many features in common. Both areas are concerned with the motion of robotic mechanisms, and more importantly planning and control methods both determine a representation that maps robot state to robot motion. In the case of feedback control, this representation is a potential function defined for a given region of the state space. The gradient of the potential function at a specific state encodes the motion command. In contrast, motion planning determines motion plans. These motion plans also encode motions for a set of states.

Motion planning and feedback control also differ in certain aspects. A motion planner generally makes stronger assumptions than a controller about the environment, the ability to assess its state, and the changes that can occur in the environment. Motion planning also requires the ability to project the robot's state into the

future, given its current state and a particular action. By using this ability together with global information about the environment, motion planners can determine motions that are not susceptible to local minima. This positive characteristic of motion planners, however, results in significantly increased computational cost (Chap. 7). The large discrepancy in computational requirements for planning and control and the resulting divergence of computational techniques may explain the current separation of the two fields. Researchers are beginning to attempt to reverse this separation by devising a unified theory of planning and control.

36.5.1 Feedback Motion Planning

Feedback motion planning combines planning and feedback into a single motion strategy. A planner considers global information to compute a feedback motion plan free of local minima. Such a feedback motion plan can be interpreted as a potential function or vector field whose gradient will lead the robot to the goal state from any reachable part of the state space [36.18]. Local minima-free potential functions are also called navigation functions [36.131, 132]. Given the current state of the robot and the global navigation function, feedback control is used to determine the robot's motion. The consideration of feedback about the robot's state in the context of a global navigation function reduces the susceptibility to sensing and actuation uncertainty.

Feedback motion planning, in principle, can address the entire spectrum of motion constraints and their feedback requirements (Fig. 36.3). Given a global navigation function that considers all motion constraints, the feedback requirements can easily be satisfied, since the feedback motion plan already specifies the desired motion command for the entire state space. Obviously, the major challenge in feedback motion planning is the computation of such a navigation function or feedback motion plan. The problem becomes particularly difficult in the context of a manipulation task, since the state space (or configuration space) changes each time the robot grasps or releases an object in the environment (Sect. 36.3). This change makes it necessary to recompute the feedback motion plan. Frequent recomputation is also necessary in dynamic environments, where the motion of obstacles can repeatedly invalidate a previously computed feedback motion plan.

In the remainder of this section, we will review a variety of methods for computing navigation functions. In general, the problem of efficiently computing feedback motion plans for manipulation tasks remains unsolved. We therefore also present methods that do not explicitly

consider manipulation. These methods can be divided into three categories: (1) exact methods, (2) approximate methods based on dynamic programming, and (3) approximate methods based on composing and sequencing simpler potential functions.

The earliest exact methods for the computation of navigation functions are applicable to simple environments with obstacles of specific shapes [36.131–133]. Approximate methods based on discretized spaces (grids) overcome this limitation but possess an exponential computational complexity in the number of dimensions of the state space. These approximate navigation functions are called numerical navigation functions [36.134]. These navigation functions are often used for applications in mobile robotics. Due to the low-dimensional configuration space associated with mobile robots, they can generally solve motion planning problems robustly and efficiently.

Some physical processes, such as heat transfer or fluid flow, can be described by a specific type of differential equation, called harmonic functions. These functions possess properties that make them suitable as navigation functions [36.135–139]. Navigation functions based on harmonic functions are most commonly computed in an approximate, iterative fashion. The requirement for iterative computation increases the computational cost relative to the simpler numerical navigation functions [36.134].

More recent methods for the computation of numerical navigation functions consider differential motion constraints at a significantly reduced computational cost [36.140]. These methods rely on classical numerical dynamic programming techniques and numerical optimal control. However, in spite of their reduced computational complexity, these methods remain too computationally costly to be applied to manipulation tasks with many degrees of freedom in dynamic environments.

Navigation functions can also be computed by composing local potential functions based on global information. This is illustrated in Fig. 36.22. The goal is to compute a navigation function for the entire configuration space C . This is accomplished by sequencing overlapping funnels. Each of the funnels represents a simple, local potential function. By following the gradient of this potential function, motion commands can be determined for a subset of the configuration space. If the funnels are sequenced correctly, the composition of local funnels can yield a global feedback plan. This feedback plan can be viewed as a hybrid system [36.141] in which the sequencing of funnels represents a discrete transition structure, whereas the individual controllers operate in a continuous domain. The composition of funnels is considered planning. The

consideration of global information during the planning permits to determine a funnel composition that avoids local minima.

One of the earliest methods based on the global composition of local funnels was proposed by *Choi and Latombe* [36.142]. In this method, the state space of the robot is decomposed into convex regions. The connectivity of these regions is analyzed to determine global information about the state space. This information can be used to combine simple, local potential functions, one for each convex regions of state space, into a local minima-free potential function. More rigorous approaches based on this idea have been developed. These approaches can consider the dynamics of the robot and nonholonomic motion constraints [36.143–145]. These methods have only been applied to low-dimensional state spaces and cannot easily be applied to manipulation tasks.

The random neighborhood graph [36.146] is a sampling-based method of computing a decomposition of the overall state space. As before, a navigation function can be computed by analyzing the global connectivity of the decomposition and imposing adequate local potential functions for each subdivision. A specialized method following the same principle for planar robots in polygonal environments has also been proposed [36.147]. The idea of composing local potential functions has also been applied successfully to a complex robot control task [36.148]. Finally, in [36.149] a general and efficient method of computing a smooth feedback plan over a cylindrical algebraic decomposition of configuration space has been proposed.

The computation of a navigation function over the entire configuration space quickly becomes intractable as the dimensionality of the space increases. To overcome this challenge, in particular in the context of autonomous mobile manipulation, workspace heuristics have been employed to determine a navigation function efficiently. This navigation function does not cover the entire configuration space but only those regions heuristically determined to be relevant to the motion problem [36.150]. This method of generating feedback

Fig. 36.22 Composing funnels into a navigation function

plans is able to satisfy the various motion constraints depicted in Fig. 36.3 and their respective feedback requirements.

36.5.2 Augmenting Global Plans with Feedback

The manipulation planning techniques described in Sect. 36.3 are not susceptible to local minima, as they consider global state space information. Due to the computational complexity associated with the consideration of global information, these planning techniques are not able to satisfy the feedback requirements of manipulation tasks. However, the required frequency of feedback about global motion are relatively low: the global connectivity of the configuration space changes relatively infrequently (Fig. 36.3). It would therefore be possible to consider feedback for global motion at the slow rates the planner can accommodate, while considering feedback for other motion constraints at higher frequencies. To achieve this, global motion plans have to be augmented with reactive components that incrementally modify the global plan in response to feedback from the environment. As long as the global connectivity information captured by the plan remains valid, the incremental modifications can ensure that all other motion constraints, ranging from task requirements to reactive obstacles avoidance, are satisfied.

The elastic-band framework [36.151] augments global plans with reactive obstacle avoidance. A global configuration space path, determined by a planner, is covered with local potential functions, each of which is derived from the local distribution of obstacles around the path. These local potentials cause the path to deform so as to maintain a minimum distance from obstacles. Visually, the path behaves as an elastic band that is deformed by the motion of obstacles. The local potential functions, together with the global path, can be viewed as a navigation function for a lo-

cal region of the configuration space. Integrated with a global planner and replanner, the elastic-band framework permits real-time obstacle avoidance that is not susceptible to local minima. However, the feedback frequency for global motion remains limited by the global motion planner. Specific task constraints have not been integrated into the elastic-band framework; consequently, its application to manipulation tasks is limited.

In its original formulation, the elastic-band framework assumed that all degrees of freedom of the robot are holonomic. An extended formulation augments motion paths for nonholonomic platforms with reactive components [36.152].

The elastic-strip framework [36.153] also augments global motion plans with reactive obstacle avoidance. In addition to reactive obstacle avoidance, however, the elastic-strip framework can accommodate task constraints. Similarly to an elastic band, an elastic strip covers a global path with local potential functions. In contrast to the elastic-band framework, these potential functions are based on task-level controllers (Sect. 36.2) and therefore allow the task-consistent modification of the global path. The elastic-strip framework is therefore well suited for the execution of manipulation plans in dynamic environments. An elastic strip will be incrementally modified to represent a constraint-consistent trajectory, as long as the global information captured by the underlying plan remains valid. The elastic-strip framework has been applied to a variety of manipulation tasks on a mobile manipulation platform.

Extending the elastic-band and elastic-strips frameworks, the elastic-roadmap framework combines reactive task-level control with efficient global motion planning [36.150]. The elastic roadmap represents a hybrid system of task-level controllers that are composed into a navigation function, thereby satisfying the motion constraints depicted in Fig. 36.3 and their respective feedback requirements.

36.6 Conclusions and Further Reading

In this chapter, an overview of motion generation and control strategies in the context of robotic manipulation tasks has been provided. Issues related to modeling the interfaces between the robot and the environment at the different time scales of motion and incorporating sensing and feedback were considered. Manipulation planning was introduced as an extension to the basic motion planning problem, which can be modeled as a hybrid system of continuous configuration spaces arising from the act of grasping and moving parts in

the environment. The important example of assembly motion has been discussed through the analysis of contact states and compliant motion control. The operational space framework, as described in Sect. 36.2, permits the position and force control of operational points on a serial-chain manipulator. A number of extensions have been proposed in the literature, extending the framework to situations with multiple concurrent contact points, cooperative manipulation scenarios, and branching kinematic chains. For manipulation plan-

ning, extensions involving grasp and regrasp planning, multiple robots, multiple parts, and movable obstacles have been considered. In this section we will briefly discuss these extensions and refer to the appropriate literature.

36.6.1 General Contact Models

The hybrid force/motion control described by *Raibert* and *Craig* [36.154] has been shown to have shortcomings [36.155]. A general contact model for dynamically decoupled force/motion control in the context of operational space control that overcomes these problems has been presented in [36.155]. This general contact model has been extended into a compliant motion control framework to enable force control for multiple contact points [36.126] in nonrigid environments, and to enable force control for multiple contact points on different links of a kinematic chain [36.156]. The operational space framework for task-level control has been applied for the real-time simulation of complex dynamic environments [36.157]. Contact points between objects in the environment are modeled as operation points, resulting in a mathematically elegant framework for resolving impulses and contact constraints for moving bodies.

36.6.2 Cooperative Manipulation Control

If multiple task-level controlled robots collaborate to manipulate an object, they form a closed kinematic chain that is connected through the object. The dynamics of the entire system can be described using the notion of an augmented object [36.158, 159], in which the dynamics of the manipulators and the object are combined to form a model of the overall system. The internal forces that occur at the grasp points during motion can be modeled using the virtual linkage framework [36.160]. A number of alternative strategies for the cooperative manipulation of multiple robots outside of the operational space framework have been proposed [36.161–168].

36.6.3 Control of Branching Mechanisms

So far, we have implicitly assumed that the task-controlled robot consists of a single kinematic chain. This assumption does not hold in the case of kinematically more complex mechanisms, such as humanoid robots (Chap. 67). These robots can consist of multiple branching kinematic chains. If we consider the torso of a humanoid robot to be the robot's base, for example, then the legs, arms, and the head represent five kinematic chains attached to this base. We call such

a mechanism a branching mechanism if it does not contain any closed kinematic loops. Tasks performed by a branching mechanism may require the specification of operational points on any one of those branches; for example, while the legs perform locomotion the hands achieve a manipulation task and the head is oriented to maintain visibility of the manipulated object.

The operational space framework has been extended to task-level control of branching mechanisms [36.169]. This extension combined operational points and associated Jacobians and computes an operational space inertia matrix that combines all operational points. This matrix can be computed efficiently with an algorithm that in practice is linear in the number of operational points [36.170, 171]. More recently, the operational space framework has been applied to quadrupedal locomotion [36.172].

36.6.4 Nonholonomic Mobile Manipulation

All previously discussed work on task-level control assumes that the degrees of freedom are holonomic (Chap. 40). For manipulator arms this is generally a valid assumption. The most common type of mobility platform, however, is based on either differential drives, synchro-drives, or Ackerman steerings (point to a section), all of which are subject to nonholonomic constraints. The operational space framework has been extended to mobile manipulation platforms that combine a nonholonomic mobility platform with a holonomic manipulator arm [36.173–175], enabling the task-level control of a large class of mobile manipulation platforms.

36.6.5 Learning Models with Uncertainty

The efficacy of operational space control depends on the accuracy of the dynamic model of the robot. In particular when multiple behaviors are executed using null-space projections, modeling errors can have significant effects. To overcome the reliance on accurate dynamic models, reinforcement learning can be used to learn operational space controllers [36.176].

36.6.6 Grasping and Regrasp Planning

Deciding the intermediate stable configurations for a part necessary to complete a manipulation task and selecting proper grasps are both difficult problems in themselves that operate over a continuum of possible solutions. *Simeon* et al. developed a manipulation planning framework that considers continuous grasps and placements [36.177]. However, selecting from among all possible grasp configurations and deciding when

to regrasp is still an open research problem. For an overview of various grasp quality metrics, see *Miller* and *Allen* [36.178, 179] and Chap. 38.

36.6.7 Multiple Parts

The manipulation planning framework nicely generalizes to multiple parts, P_1, \dots, P_k . Each part has its own C -space, and C is formed by taking the Cartesian product of all the part C -spaces with the manipulator C -space. The set C_{adm} is defined in a similar way, but now part–part collisions also have to be removed, in addition to part–manipulator, manipulator–obstacle, and part–obstacle collisions. The definition of C_{stable} requires that all parts be in stable configurations; the parts may even be allowed to stack on top of each other. The definition of C_{grasp} requires that one part is grasped and all other parts are stable. There are still two modes, depending on whether the manipulator is grasping a part. Once again, transitions occur only when the robot is in $C_{\text{trans}} = C_{\text{stable}} \cap C_{\text{grasp}}$.

36.6.8 Planning for Multiple Robots

Generalizing to k robots would lead to $2k$ modes, in which each mode indicates whether each robot is grasping a part. Multiple robots may even be allowed to grasp the same part, which leads to the interesting problem of planning for closed kinematic chains and cooperative motion (Chap. 39). *Koga* addressed multi-arm manipulation planning where the same object must be grasped and moved by several manipulator arms [36.21]. Another generalization could allow a single robot to grasp more than one part simultaneously.

36.6.9 Planning for Closed Kinematic Chains

The subspace of C that results from maintaining kinematic closure arises when multiple robots grasp the same part, or even when multiple fingers of the same hand grasp a single part (Chap. 19). Planning in this context requires that paths remain on a lower-dimensional variety for which a parameterization is not available. Planning the motion of parallel mechanisms or other systems with loops typically requires maintaining multiple closure constraints simultaneously (Chap. 18).

36.6.10 Planning with Movable Obstacles

In some cases, the robot may be allowed to reposition obstacles in the environment rather than simply avoid them. *Wilfong* first addressed motion planning in the presence of movable obstacles [36.180]. *Wilfong* proved that the problem is PSPACE-hard even in two-dimensional environments where the final positions of all movable objects are specified. *Erdmann* and *Lozano-Perez* considered coordinated planning for multiple moving objects [36.181]. *Alami* et al. presented a general algorithm for the case of one robot and one movable object and formulated the space of grasping configurations into a finite number of cells [36.17]. *Chen* and *Hwang* developed a planner for a circular robot that is allowed to push objects aside as it moves [36.182]. *Stilman* and *Kuffner* considered movable obstacles in the context of navigation planning [36.183], and manipulation planning [36.184]. *Nieuwenhuisen* et al. also developed a general framework for planning with movable obstacles [36.185].

36.6.11 Nonprehensile Manipulation

Lynch and *Mason* explored scenarios in which grasping operations are replaced by pushing operations [36.186]. The space of stable pushing directions imposes nonholonomic constraints on the motion of the robot, which opens up issues related to controllability. Related issues also arise in the context of part-feeders and manipulation for manufacturing and assembly (Chap. 54).

36.6.12 Assembly Motion Extensions

The work in assembly motion described in this chapter has focused on rigid-part assembly, and the parts considered are mostly polyhedral or of simple nonpolyhedral shapes, such as round pegs and holes. More recent work on contact state analysis for curved objects can be found in [36.187]. An emerging field in assembly is micro/nanoassembly ( VIDEO 359; Chap. 27). Flexible or deformable part assembly has also begun to attract attention [36.188–190]. Virtual assembly [36.191] for simulation and prototyping is another interesting area of study.

37. Contact Modeling and Manipulation

Imin Kao, Kevin M. Lynch, Joel W. Burdick

Robotic manipulators use contact forces to grasp and manipulate objects in their environments. Fixtures rely on contacts to immobilize work-pieces. Mobile robots and humanoids use wheels or feet to generate the contact forces that allow them to locomote. Modeling of the *contact interface*, therefore, is fundamental to analysis, design, planning, and control of many robotic tasks.

This chapter presents an overview of the modeling of contact interfaces, with a particular focus on their use in manipulation tasks, including graspless or *nonprehensile* manipulation modes such as pushing. Analysis and design of grasps and fixtures also depends on contact modeling, and these are discussed in more detail in Chap. 38. Sections 37.2–37.5 focus on rigid-body models of contact. Section 37.2 describes the kinematic constraints caused by contact, and Sect. 37.3 describes the contact forces that may arise with Coulomb friction. Section 37.4 provides examples of analysis of multicontact manipulation tasks with rigid bodies and Coulomb friction. Section 37.5 extends the analysis to manipulation by pushing. Section 37.6 introduces modeling of contact interfaces, kinematic duality, and pressure distribution and soft contact interface. Section 37.7 describes the concept of the friction limit surface and illustrates it with an example demonstrating the construction of a limit surface for a soft contact. Finally, Sect. 37.8 discusses how these more accurate models can be used in fixture analysis and design.

37.1 Overview

A contact model characterizes both the forces that can be transmitted through the contact as well as the allowed

relative motions of the contacting bodies. These characteristics are determined by the geometry of the con-

tacting surfaces and the material properties of the parts, which dictate friction and possible contact deformation.

37.1.1 Choosing a Contact Model

The choice of a contact model largely depends upon the application or analysis that must be carried out. When appropriate analytical models are used, one can determine if a manipulation plan or fixture design meets desired functional requirements within the model's limits.

Rigid-Body Models

Many approaches to manipulation, grasp, and fixture analysis are based on rigid-body models. In the rigid-body model, no deformations are allowed at the points or surfaces of contact between two bodies. Instead, contact forces arise from two sources: the constraint of incompressibility and impenetrability between the rigid bodies, and surface frictional forces. Rigid-body models are straightforward to use, lead to computationally efficient planning algorithms, and are compatible with solid-modeling software systems. Rigid-body models are often appropriate for answering qualitative questions such as *will this fixture be able to hold my workpiece?* and for problems involving stiff parts with low to moderate contact forces.

Rigid-body models are not capable of describing the full range of contact phenomena, however; for example, rigid-body models cannot predict the individual contact forces of a multiple-contact fixture (the static indeterminacy problem [37.1, 2]). Furthermore, workpieces held in fixtures experience non-negligible deformations in many high-force manufacturing operations [37.3–6]. These deformations, which crucially impact machining accuracy, cannot be determined from rigid-body models. Also, a rigid-body model augmented with a Coulomb friction model can lead to mechanics problems that have no solution or multiple solutions [37.7–15]. To overcome the limitations inherent in the rigid-body model, one must introduce compliance into the contact model.

Compliant Models

A *compliant* contact deforms under the influence of applied forces. The forces of interaction at the contact are

derived from the *compliance* or *stiffness* model. While compliant contact models are typically more complicated, they have several advantages: they overcome the static indeterminacy inherent to rigid-body models and they predict the deformations of grasped or fixtured parts during loading.

A detailed model of the deformations of real materials can be quite complex. Consequently, for analysis we often introduce *lumped-parameter* or *reduced-order* compliance models having a limited number of variables. In this chapter we summarize a reduced-order *quasi-rigid-body* approach to modeling that can model a variety of compliant materials in a way that is consistent with both the solid mechanics literature and conventional robot analysis and planning paradigms.

Finally, three-dimensional finite-element models [37.16–18] or similar ideas [37.19, 20] can be used to analyze workpiece deformations and stresses in fixtures. While accurate, these numerical approaches have some drawbacks, for example, the grasp stiffness matrix can only be found through difficult numerical procedures. Stiffness matrices are often needed to compute quality measures that are the basis for optimal grasping plans or fixturing designs [37.21, 22]. Thus, these numerical approaches are better suited for verifying final fixture designs.

37.1.2 Grasp/Manipulation Analysis

Once a contact model has been chosen, we can use it to analyze tasks involving multiple contacts. If a part is subject to multiple contacts, the kinematic constraints and force freedoms due to the individual contacts must be combined. This combined analysis facilitates manipulation planning – choosing the contact locations, and possibly the motions or forces applied by those contacts, to achieve the desired behavior of the part. A prime example is the grasping or fixturing problem: choosing contact locations, and possibly contact forces, to prevent motion of a part in the face of external disturbances. This well-studied topic is discussed in greater detail in Chap. 38. Other examples include problems of partial constraint, such as pushing a part or inserting a peg into a hole.

37.2 Kinematics of Rigid-Body Contact

Contact kinematics is the study of how two or more parts can move relative to each other while respecting the rigid-body impenetrability constraint. It also classifies motion in contact as either rolling or slipping.

Consider two rigid bodies whose position and orientation (configuration) is given by the local coordinate column vectors \mathbf{q}_1 and \mathbf{q}_2 , respectively. Writing the composite configuration as $\mathbf{q} = (\mathbf{q}_1^T, \mathbf{q}_2^T)^T$, we de-

fine a *distance* function $d(\mathbf{q})$ between the parts that is positive when they are separated, zero when they are touching, and negative when they are in penetration. When $d(\mathbf{q}) > 0$, there are no constraints on the motions of the parts. When the parts are in contact ($d(\mathbf{q}) = 0$), we look at the time derivatives \dot{d} , \ddot{d} , etc., to determine if the parts stay in contact or break apart as they follow a trajectory $\mathbf{q}(t)$. This can be determined by the following table of possibilities

d	\dot{d}	\ddot{d}	...
> 0			no contact,
< 0			infeasible (penetration),
$= 0$	> 0		breaking contact,
$= 0$	< 0		infeasible (penetration),
$= 0$	$= 0$	> 0	breaking contact,
$= 0$	$= 0$	< 0	infeasible (penetration),
etc.			

The contact is maintained only if all time derivatives are zero.

The first two time derivatives are written

$$\dot{d} = \left(\frac{\partial d}{\partial \mathbf{q}} \right)^T \dot{\mathbf{q}}, \quad (37.1)$$

$$\ddot{d} = \dot{\mathbf{q}}^T \frac{\partial^2 d}{\partial \mathbf{q}^2} \dot{\mathbf{q}} + \left(\frac{\partial d}{\partial \mathbf{q}} \right)^T \ddot{\mathbf{q}}. \quad (37.2)$$

The terms $\partial d / \partial \mathbf{q}$ and $\partial^2 d / \partial \mathbf{q}^2$ carry information about the local contact geometry. The former corresponds to the contact normal, while the latter corresponds to the relative curvature of the parts at the contact.

If contact is maintained, we can classify the contact as slipping or rolling. Analogous to the table above, the contact is rolling if and only if there is zero relative tangential velocity, acceleration, etc., between the contact points on the parts. If the relative tangential velocity is nonzero, the parts are slipping; if the relative velocity is zero but relative tangential acceleration or (higher-order derivatives) is not, slipping is incipient.

In this section we focus on a *first-order* analysis of contact kinematics. A first-order analysis concludes that contact is maintained if $d(\mathbf{q}) = 0$ and $\dot{d} = 0$. This local linearization of contact kinematics focuses on the velocity $\dot{\mathbf{q}}$ and the contact normal in $\partial d / \partial \mathbf{q}$; higher-order spatial derivatives of the contact geometry (curvature, etc.) are not considered. While this is a good starting point, it may occasionally lead to erroneous conclusions. For example, *Rimon and Burdick* [37.23–25] showed that a first-order analysis may incorrectly predict mobility of a part in a fixture when a second-order analysis shows that it is in fact completely constrained.

Analysis of the kinematics of rolling contact of parameterized surfaces can be found in [37.26]; see also [37.27–30].

37.2.1 Contact Constraints

As described in Chap. 2, a rigid body in space has six degrees of freedom, specified by the location of the origin of a coordinate frame P affixed to the part and the orientation of this coordinate frame relative to an inertial frame O fixed in the world. Let ${}^O\mathbf{p}_P \in \mathbb{R}^3$ be the position of the part center of mass and ${}^O\mathbf{R}_P \in SO(3)$ be the rotation matrix describing the orientation of the part relative to O . The spatial velocity of the part can be written as $\mathbf{t} \in \mathbb{R}^6$, sometimes called a *twist*,

$$\mathbf{t} = (\boldsymbol{\omega}^T, \mathbf{v}^T)^T,$$

where $\boldsymbol{\omega} = (\omega_x, \omega_y, \omega_z)^T$ and $\mathbf{v} = (v_x, v_y, v_z)^T$ give the angular velocity and linear velocity of P in the world frame O , respectively, such that $\boldsymbol{\omega}$ satisfies

$${}^O\dot{\mathbf{R}}_P = \boldsymbol{\omega} \times {}^O\mathbf{R}_P$$

and \mathbf{v} satisfies

$$\mathbf{v} = {}^O\dot{\mathbf{p}}_P - \boldsymbol{\omega} \times {}^O\mathbf{p}_P.$$

It is worth taking a moment to really understand the spatial velocity of a body. It consists of the body's angular velocity expressed in the world frame O , along with the linear velocity of a point as if it were rigidly attached to the body but currently at the origin of the world frame. This point need not be physically on the body. In other words, \mathbf{v} is not simply ${}^O\dot{\mathbf{p}}_P$. This notation will simplify the following expressions, where all velocities and forces will be expressed in the common world frame O . (Be aware that twists are sometimes defined in a body frame instead.)

A point contact acting on the part provides a unilateral constraint which prevents the part from locally moving against the contact normal. Let \mathbf{x} be the location of the contact in O . The linear velocity of the point on the part in contact is

$$\mathbf{v}_C = \mathbf{v} + \boldsymbol{\omega} \times \mathbf{x}.$$

(We drop the pre-superscripts O for simplicity; for example, ${}^O\mathbf{x}$ is written simply as \mathbf{x} .) Let $\hat{\mathbf{u}}$ be the unit vector normal pointing into the part (Fig. 37.1). The first-order condition that the part not move into the unilateral constraint can be written

$$\mathbf{v}_C^T \hat{\mathbf{u}} = (\mathbf{v} + \boldsymbol{\omega} \times \mathbf{x})^T \hat{\mathbf{u}} \geq 0. \quad (37.3)$$

Fig. 37.1 Notation for a part in contact with a manipulator or the environment

In other words, the velocity of the part at C cannot have a component in the opposite direction of the contact normal. To write this another way, define a generalized force or *wrench* w consisting of the torque m and force f acting on the part for a unit force along the contact normal

$$w = (m^T, f^T)^T = [(x \times \hat{u})^T, \hat{u}^T]^T.$$

Then (37.3) can be rewritten as

$$t^T w \geq 0. \quad (37.4)$$

If the external constraint point is moving with linear velocity v_{ext} , (37.4) changes to

$$t^T w \geq v_{\text{ext}}^T \hat{u}, \quad (37.5)$$

which reduces to (37.4) if the constraint is stationary.

Each inequality of the form (37.5) constrains the velocity of the part to a half-space of its six-dimensional velocity space bounded by the hyperplane $t^T w = v_{\text{ext}}^T \hat{u}$. Unioning the set of all constraints, we get a convex polyhedral set of feasible part velocities. A constraint is redundant if its half-space constraint does not change the feasible velocity polyhedron. For a given twist t , a constraint is active if

$$t^T w = v_{\text{ext}}^T \hat{u}; \quad (37.6)$$

otherwise the part is breaking contact at that point. In general, the feasible velocity polyhedron for a part can consist of a six-dimensional interior (where no contact constraint is active), five-dimensional hyperfaces, four-dimensional hyperfaces, and so on, down to one-dimensional edges and zero-dimensional points. A part velocity on an n -dimensional facet of the velocity polyhedron indicates that $6 - n$ independent (nonredundant) constraints are active.

If all of the constraints are stationary ($v_{\text{ext}} = 0$), then the boundary of each half-space defined by (37.5)

passes through the origin of the velocity space, and the feasible velocity set becomes a cone rooted at the origin. Let w_i be the constraint wrench of stationary contact i . Then the feasible velocity cone is

$$V = \{t \mid t^T w_i \geq 0 \quad \forall i\}.$$

If the w_i span the six-dimensional generalized force space, or, equivalently, the convex hull of the w_i contains the origin in the interior, then V is the null set, the stationary contacts completely constrain the motion of the part, and we have form closure, as discussed in Chap. 38.

In the discussion above, each constraint (37.5) divides the part velocity space into three categories: a hyperplane of velocities that maintain contact, a half-space of velocities that separate the parts, and a half-space of velocities that cause the parts to penetrate. Velocities where the contact is maintained can be further broken down into two categories: velocities where the part slips over the contact constraint, and velocities where the part sticks or rolls on the constraint. In the latter case, the part velocity satisfies the three equations

$$v + \omega \times x = v_{\text{ext}}. \quad (37.7)$$

Now we can give each point contact i a label m_i corresponding to the type of contact, called the contact label: b if the contact is breaking, f if the contact is fixed (including rolling), and s if the contact is slipping, i.e., (37.6) is satisfied but (37.7) is not. The *contact mode* for the entire system can be written as the concatenation of the contact labels at the k contacts, $m_1 m_2 \dots m_k$.

37.2.2 Collections of Parts

The discussion above can be generalized to find the feasible velocities of multiple parts in contact. If parts i and j make contact at a point x , where \hat{u}_i points into part i and $w_i = [(x \times \hat{u}_i)^T, \hat{u}_i^T]^T$, then their spatial velocities t_i and t_j must satisfy the constraint

$$(t_i - t_j)^T w_i \geq 0 \quad (37.8)$$

to avoid penetration. This is a homogeneous half-space constraint in the composite (t_i, t_j) velocity space. In an assembly of multiple parts, each pairwise contact contributes another constraint in the composite part velocity space, and the result is a polyhedral convex cone of kinematically feasible velocities rooted at the origin of the composite velocity space. The contact mode for the entire assembly is the concatenation of the contact labels at each contact in the assembly.

37.3 Forces and Friction

A commonly used model of friction in robotic manipulation is Coulomb's law [37.32]. This experimental law states that the friction force magnitude f_t in the tangent plane at the contact interface is related to the normal force magnitude f_n by $f_t \leq \mu f_n$, where μ is called the friction coefficient. If the contact is sliding, then $f_t = \mu f_n$, and the friction force opposes the direction of motion. The friction force is independent of the speed of sliding.

Often two friction coefficients are defined, a static friction coefficient μ_s and a kinetic (or sliding) friction coefficient μ_k , where $\mu_s \geq \mu_k$. This implies that a larger friction force may be available to resist initial motion, but once motion has begun, the resisting force decreases. Many other friction models have been developed with different functional dependencies on factors such as the speed of sliding and the duration of static contact before sliding. All of these are aggregate models of complex microscopic behavior. For simplicity, we will assume the simplest Coulomb friction model with a single friction coefficient μ . This model is reasonable for hard, dry materials. The friction coefficient depends on the two materials in contact, and typically ranges from 0.1 to 1.

Figure 37.3a shows that this friction law can be interpreted in terms of a *friction cone*. The set of all forces that can be applied to the disk by the supporting

line is constrained to be inside this cone. Correspondingly, any force the disk applies to the support is inside the negative of the cone. The half-angle of the cone is $\beta = \tan^{-1} \mu$, as shown in Fig. 37.4. If the disk slips to the left on the support, the force the support applies to it acts on the right edge of the friction cone, with a magnitude determined by the normal force.

If we choose a coordinate frame, the force \mathbf{f} applied to the disk by the support can be expressed as a wrench $\mathbf{w} = [(\mathbf{x} \times \mathbf{f})^T, f^T]^T$, where \mathbf{x} is the contact location. Thus the friction cone turns into a wrench cone, as shown in Fig. 37.3b. The two edges of the planar friction cone give two half-lines in the wrench space, and the wrenches that can be transmitted to the part through the contact are all nonnegative linear combinations of basis vectors along these edges. If \mathbf{w}_1 and \mathbf{w}_2 are basis vectors for these wrench cone edges, we write the wrench cone as

$$\mathcal{WC} = \{k_1 \mathbf{w}_1 + k_2 \mathbf{w}_2 \mid k_1, k_2 \geq 0\}.$$

If there are multiple contacts acting on a part, then the total set of wrenches that can be transmitted to the part through the contacts is the nonnegative linear combination of all the individual wrench cones \mathcal{WC}_i ,

$$\begin{aligned} \mathcal{WC} &= \text{pos}(\{\mathcal{WC}_i\}) \\ &= \left\{ \sum_i k_i \mathbf{w}_i \mid \mathbf{w}_i \in \mathcal{WC}_i, k_i \geq 0 \right\}. \end{aligned}$$

This composite wrench cone is a convex polyhedral cone rooted at the origin. An example composite

Fig. 37.3 (a) A planar friction cone. (b) The corresponding wrench cone. (c) An example composite wrench cone resulting from two frictional contacts

Fig. 37.4 (a) A spatial friction cone. The half-angle of the cone is $\beta = \tan^{-1} \mu$. (b) An inscribed pyramidal approximation to the friction cone. A more accurate inscribed pyramidal approximation can be used by increasing the number of faces of the pyramid. Depending on the application, a circumscribed pyramid could be used instead of an inscribed pyramid

wrench cone arising from two planar frictional contacts is shown in Fig. 37.3c. If the composite wrench cone is the entire wrench space, then the contacts can provide a force-closure grasp (Chap. 38).

In the spatial case, the friction cone is a circular cone, defined by

$$\sqrt{f_x^2 + f_y^2} \leq \mu f_z, \quad f_z \geq 0, \quad (37.9)$$

when the contact normal is in the $+z$ -direction (Fig. 37.4). The resulting wrench cone, and composite wrench cone $\text{pos}(\{\mathcal{WC}_i\})$ for multiple contacts, is a convex cone rooted at the origin, but it is not polyhedral. For computational purposes, it is common to approximate circular friction cones as pyramidal cones, as shown in Fig. 37.4. Then individual and composite wrench cones become polyhedral convex cones in the six-dimensional wrench space.

If a contact or set of contacts acting on a part is ideally force controlled, the wrench \mathbf{w}_{ext} specified by the controller must lie within the composite wrench cone corresponding to those contacts. Because these force-controlled contacts choose a subset of wrenches (possibly a single wrench) from this wrench cone, the total composite wrench cone that can act on the part (including other non-force-controlled contacts) may no longer be a homogeneous cone rooted at the origin. This is roughly analogous to the case of velocity-controlled contacts in Sect. 37.2.1, which results in a feasible twist set for the part that is not a cone rooted at the origin. Ideal robot manipulators may be controlled by position control, force control, hybrid position–force control, or some other scheme. The control method must be compatible with the parts' contacts with each other and the environment to prevent excessive forces [37.33].

37.3.1 Graphical Planar Methods

Just as homogeneous twist cones for planar problems can be represented as convex signed (+ or –) COR regions in the plane, homogeneous wrench cones for planar problems can be represented as convex signed regions in the plane. This is called *moment labeling* [37.14, 34]. Given a collection of lines of force in the plane (e.g., the edges of friction cones from a set of point contacts), the set of all nonnegative linear combinations of these can be represented by labeling all the points in the plane with either a + if all resultants make nonnegative moment about that point, a – if all make nonpositive moment about that point, a \pm if all make zero moment about that point, and a blank label if there exist resultants making positive moment and resultants making negative moment about that point.

The idea is best illustrated by an example. In Fig. 37.5a, a single line of force is represented by labeling the points to the left of the line with a + and points to the right of the line with a –. Points on the line are labeled \pm . In Fig. 37.5b, another line of force is added. Only the points in the plane that are consistently labeled for both lines of force retain their labels; inconsistently labeled points lose their labels. Finally, a third line of force is added in Fig. 37.5c. The result is a single region labeled +. A nonnegative combination of the three lines of force can create any line of force in the plane that passes around this region in a counterclockwise sense. This representation is equivalent to a homogeneous convex wrench cone representation.

37.3.2 Duality of Contact Wrenches and Twist Freedoms

Our discussion of kinematic constraints and friction should make it apparent that, for any point contact and contact label, the number of equality constraints on the part's motion caused by that contact is equal to the number of wrench freedoms it provides. For example, a breaking contact \mathbf{b} provides zero equality constraints on the part motion and also allows no contact force. A fixed contact \mathbf{f} provides three motion constraints (the motion of a point on the part is specified) and three freedoms on the contact force: any wrench in the interior of the contact wrench cone is consistent with the contact mode. Finally, a slipping contact \mathbf{s} provides one equality motion constraint (one equation on the part's motion must be satisfied to maintain the contact), and for a given motion satisfying the constraint, the contact wrench has only one freedom, the magnitude of the contact wrench on the edge of the friction cone and opposite the slipping direction. In the planar case, the motion constraints and wrench freedoms for \mathbf{b} , \mathbf{s} , and \mathbf{f} contacts are zero, one, and two, respectively.

Fig. 37.5 (a) Representing a line of force by moment labels. (b) Representing the nonnegative linear combinations of two lines of force by moment labels. (c) Nonnegative linear combinations of three lines of force

Table 37.1 Duality of the kinematics of contact interface. The force/motion relationships for finger and grasped object are dual to each other in the joint space, contact interface, and the Cartesian space of the object. In this table, the notation of θ , \mathbf{x}_f , \mathbf{x}_p , and \mathbf{x}_b are the displacement in the joint space, the Cartesian space at the contact point on the finger, the Cartesian space at the contact point on the object, and the reference frame on the object, respectively, with \mathbf{x}_{tr} denoting the transmitted components. The δ prefix denotes infinitesimal changes in the named coordinates. The forces with corresponding subscripts are referenced to the corresponding coordinates as those of the displacement described before

Motion	$\mathbf{J}_0 \quad \delta\theta = \delta\mathbf{x}_f$ ($6 \times m$)($m \times 1$) (6×1)	$\mathbf{H} \quad \delta\mathbf{x}_f = \delta\mathbf{x}_{tr} = \mathbf{H} \quad \delta\mathbf{x}_p$ ($n \times 6$)(6×1) ($n \times 1$) ($n \times 6$)(6×1)	$\mathbf{J}_c \quad \delta\mathbf{x}_b = \delta\mathbf{x}_p$ (6×6)(6×1) (6×1)
	Joints	Contact	Object
Force	$\mathbf{J}_0^T \quad \mathbf{f}_f = \boldsymbol{\tau}$ ($m \times 6$)(6×1) ($m \times 1$)	$\mathbf{f}_f = \mathbf{H}^T \quad \mathbf{f}_{tr} = \mathbf{f}_p$ (6×1) ($6 \times n$)($n \times 1$) (6×1)	$\mathbf{J}_c^T \quad \mathbf{f}_p = \mathbf{f}_b$ (6×6)(6×1) (6×1)

At each contact, the force and velocity constraints can be represented by an $n \times 6$ *constraint* or *selection* matrix, \mathbf{H} [37.3], at the contact interface. This constraint matrix works like a filter to transmit or deny certain components of motion across the contact interface. By the same token, forces/moments applied across the contact interface are also filtered by the same constraint matrix, \mathbf{H}^T , in a dual relationship. Three typical contact models are illustrated below. Contact forces and wrenches are measured in a frame at the contact, with the contact normal in the $+z$ -direction:

- The *point contact without friction* model. Only a normal force f_z can be exerted between the contacting bodies

$$f_z \geq 0, \quad \mathbf{w} = \mathbf{H}^T f_z = (0 \ 0 \ 1 \ 0 \ 0 \ 0)^T f_z. \quad (37.10)$$

- The *point contact with friction* model includes tangential friction forces, f_x and f_y , in addition to normal force f_z ,

$$f_z \geq 0; |f_t| = \sqrt{f_x^2 + f_y^2} \leq \mu f_z,$$

$$\mathbf{w} = \mathbf{H}^T \begin{pmatrix} f_x \\ f_y \\ f_z \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} f_x \\ f_y \\ f_z \end{pmatrix}, \quad (37.11)$$

where f_x and f_y are the x - and y -components of the tangential contact force, and f_z is the normal force.

- The *soft finger* contact model with a finite contact patch allows, in addition to the friction and normal forces, a torsional moment with respect to the con-

tact normal [37.35–39]. We have

$$f_z \geq 0;$$

$$\mathbf{w} = \mathbf{H}^T \begin{pmatrix} f_x \\ f_y \\ f_z \\ m_z \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} f_x \\ f_y \\ f_z \\ m_z \end{pmatrix}, \quad (37.12)$$

where m_z is the moment with respect to the normal of contact. The finite contact area assumed by the soft contact interface results in the application of a friction moment in addition to the traction forces. If the resultant force on the tangential plane of contact is denoted as

$$f_t = \sqrt{f_x^2 + f_y^2}$$

and the moment with respect to the contact normal is m_z , the following elliptical equation represents the relationship between the force and moment at the onset of sliding

$$\frac{f_t^2}{a^2} + \frac{m_z^2}{b^2} = 1, \quad (37.13)$$

where $a = \mu f_z$ is the maximum friction force, and $b = (m_z)_{\max}$ is the maximum moment defined in equation (37.36). Further readings on this subject can be found in [37.35–42].

As can be appreciated from the three cases above, the rows of \mathbf{H} are the directions along which contact forces are supported. Conversely, relative motions of the two objects are constrained along these same directions: $\mathbf{H}\dot{\mathbf{q}} = 0$. Thus, the constraint matrix works like a kinematic filter which dictates the components

of motions that can be transmitted through the contact interface. The introduction of this matrix makes it easy to model the contact mechanics in analysis using the dual kinematic relationship between force/moment and motion, as described in Table 37.1. For example, the constraint filter matrix in (37.12) describes that all three components of forces and one component of the moment with respect to the normal of contact can be transmitted through the contact interface of a soft finger.

In Chap. 38, when multiple contacts are considered, such \mathbf{H} matrices associated with each finger can be concatenated in an augmented matrix to work in con-

junction with the grasp and Jacobian matrices for the analysis of grasping and manipulation.

Table 37.1 summarizes the dual relationship between the force/moment and displacement – a result that is derived from the principle of virtual work. In Table 37.1, \mathbf{J}_θ is the joint Jacobian matrix relating joint velocities to fingertip velocities, and \mathbf{J}_c is the Cartesian coordinate transformation matrix relating the contact point with the centroidal coordinates of the grasped object. In addition, the number of degrees of freedom (DOFs) in the task space is n and the number of DOFs in the joint spaces is m .

37.4 Rigid-Body Mechanics with Friction

The manipulation planning problem is to choose the motions or forces applied by manipulator contacts so that the part (or parts) moves as desired. This requires solving the subproblem of determining the motion of parts given a particular manipulator action.

Let $\mathbf{q} \in \mathbb{R}^n$ be local coordinates describing the combined configuration of the system consisting of one or more parts and robot manipulators, and let $\mathbf{w}_i \in \mathbb{R}^6$ represent a wrench at an active contact i , measured in the common coordinate frame O . Let $\mathbf{w}_{\text{all}} \in \mathbb{R}^{6k}$ be the vector obtained by stacking the \mathbf{w}_i , $\mathbf{w}_{\text{all}} = (\mathbf{w}_1^T, \mathbf{w}_2^T, \dots, \mathbf{w}_k^T)^T$ (where there are k contacts), and let $\mathbf{A}(\mathbf{q}) \in \mathbb{R}^{n \times 6k}$ be a matrix indicating how (or if) each contact wrench acts on each part. (Note that a contact wrench \mathbf{w}_i acting on one part means that there is a contact wrench $-\mathbf{w}_i$ acting on the other part in contact.) The problem is to find the contact forces \mathbf{w}_{all} and the system acceleration $\ddot{\mathbf{q}}$, given the state of the system $(\mathbf{q}, \dot{\mathbf{q}})$, the system mass matrix $\mathbf{M}(\mathbf{q})$ and resulting Coriolis matrix $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$, the gravitational forces $\mathbf{g}(\mathbf{q})$, the control forces $\boldsymbol{\tau}$, and the matrix $\mathbf{T}(\mathbf{q})$ indicating how the control forces $\boldsymbol{\tau}$ act on the system. (Alternatively, if we view the manipulators as position controlled, the manipulator components of $\ddot{\mathbf{q}}$ can be directly specified and the corresponding components of the control forces $\boldsymbol{\tau}$ solved for.) One way to solve this problem is to (a) enumerate the set of all possible contact modes for the current active contacts, and (b) for each contact mode, determine if there are wrenches \mathbf{w}_{all} and accelerations $\ddot{\mathbf{q}}$ that satisfy the dynamics

$$\mathbf{A}(\mathbf{q})\mathbf{w}_{\text{all}} + \mathbf{T}(\mathbf{q})\boldsymbol{\tau} - \mathbf{g}(\mathbf{q}) = \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}. \quad (37.14)$$

and that are consistent with the contact mode's kinematic constraints (constraints on $\ddot{\mathbf{q}}$) and friction cone force constraints (constraints on \mathbf{w}_{all}). This for-

mulation is quite general and applies to multiple parts in contact. Equation (37.14) may be simplified by appropriate representations of the configurations and velocities of rigid-body parts (for example, using angular velocities of the rigid bodies instead of derivatives of local angular coordinates).

This formulation leads to some surprising conclusions: there may be multiple solutions to a particular problem (ambiguity) or there may be no solutions (inconsistency) [37.7–14]. This strange behavior arises from the status of Coulomb's law as an approximate law, and it disappears for zero friction, or friction that is small enough. Despite this weakness of the Coulomb friction law, it is a useful approximation. Nonetheless, if we would like to prove (under the Coulomb model) that a particular desired part motion occurs, we generally must also show that no other motion can occur. Otherwise we have only shown that the desired motion is one of the possible outcomes.

37.4.1 Complementarity

The conditions that each contact provides an equal number of motion constraints and wrench freedoms (Sect. 37.3.2) can be written as *complementarity* conditions. Thus the problem of solving (37.14), subject to contact constraints, can be formulated as a complementarity problem (CP) [37.12, 13, 43–46]. For planar problems, or spatial problems with approximate pyramidal friction cones, the problem is a linear complementarity problem [37.47]. For circular spatial friction cones, the problem is a nonlinear complementarity problem, due to the quadratic constraints describing the cones. In either case, standard algorithms can be used to solve for possible contact modes and part motions.

Alternatively, assuming linearized friction cones, we can formulate a linear constraint satisfaction program (LCSP) for each contact mode (e.g., a linear program with no objective function). The contact mode places linear constraints on the part accelerations, and the solver solves for the part accelerations and the non-negative coefficients multiplying each of the edges of the friction cones, subject to the dynamics (37.14). Each LCSP with a feasible solution represents a feasible contact mode.

37.4.2 Quasistatic Assumption

A common assumption in robot manipulation planning is the *quasistatic* assumption. This assumption says that parts move slowly enough that inertial effects are negligible. This means that the right- and left-hand sides of (37.14) are zero. With this assumption, we often solve for part *velocities* rather than accelerations. These velocities must be consistent with the kinematic constraints and force constraints, and forces acting on the parts must always sum to zero.

37.4.3 Examples

While rigid-body mechanics problems with friction are usually solved using computational tools for CPs and LCSPs, equivalent graphical methods can be used for some planar problems to assist the intuition. As a simple example, consider the pipe clamp in Fig. 37.6 [37.14]. Under the external wrench w_{ext} , does the clamp slide down the pipe, or does it remain fixed in place? The figure uses moment labeling to represent the composite wrench cone of contact forces that can act on the clamp from the pipe. The wrench w_{ext} acting on the clamp can be exactly balanced by a wrench in the com-

Fig. 37.6 The moment-labeling representation of the composite wrench cone of contact forces the pipe can apply to the pipe clamp. In this figure, the wrench w_{ext} applied to the pipe clamp can be resisted by forces within the composite wrench cone

posite wrench cone. This is evident from the fact that the wrench opposing w_{ext} passes around the + labeled region in a counterclockwise sense, meaning that it is contained in the contact wrench cone. As a result, static equilibrium (the ff contact mode) is a feasible solution for the pipe clamp. To arrive at the same result using an LCSP, label the unit wrenches at the edges of the friction cones w_1, \dots, w_4 . Then the clamp can remain at rest if there exist coefficients a_1, \dots, a_4 such that

$$a_1, a_2, a_3, a_4 \geq 0, \\ a_1 w_1 + a_2 w_2 + a_3 w_3 + a_4 w_4 + w_{\text{ext}} = 0.$$

To show that static equilibrium is the only solution, all other contact modes must be ruled out. Note that, if the friction coefficient at the contacts is too small, the clamp will fall under w_{ext} .

Analysis of the classic peg-in-hole problem is similar to that of the pipe clamp. Figure 37.7a shows an angled peg making two-point contact with the hole. If we apply the wrench w_1 , the forces from the two-point contact cannot resist, so the ff mode contact mode is not a possibility, and the peg will continue to move into the hole. If we apply the wrench w_2 , however, the contacts can resist, and the peg will get stuck. This is called *jamming* [37.48]. If there is higher friction at the contacts, as in Fig. 37.7b, then each friction cone may be able to see the base of the other, and the feasible contact wrenches span the entire wrench space [37.49]. In this case, any wrench we apply may be resisted by the contacts. The peg is said to be *wedged* [37.48]. Whether or not the peg will actually resist our applied wrench depends on how much internal force acts between the contacts. This cannot be answered by our rigid-body model; it requires a compliant contact model, as discussed in Sect. 37.6.

As a slightly more complex quasistatic example, consider a block on a table being pushed by a finger

Fig. 37.7 (a) The peg will proceed into the hole under the external wrench w_1 but will get stuck under the wrench w_2 . (b) The peg is wedged

Fig. 37.8 (a) A finger moves *left* into a planar block resting on a table in gravity. The contact friction cones are shown. (b) Possible contact forces for the contact label f at the leftmost bottom contact, b at the rightmost bottom contact, and s_r at the pushing contact. This contact mode $f b s_r$ corresponds to the block tipping over the leftmost contact. Note that the contact wrench cone (represented by moment labels) can provide a force that exactly balances the gravitational force. Thus this contact mode is quasistatically possible. (c) The contact wrench cone for the $s_1 s_1 f$ contact mode (block slides *left* on the table) cannot balance the gravitational force. This contact mode is not quasistatically possible. (d) The contact wrench cone for the $s_1 b s_r$ contact mode (block slides and tips) is not quasistatically possible

that moves horizontally to the left (Fig. 37.8) [37.50, 51]. Does the part begin to tip over, slide, or both tip and slide? The corresponding contact modes are $f b s_r$, $s_1 s_1 f$, and $s_1 b s_r$, as shown in Fig. 37.8. The figure also shows the composite contact wrench cones using moment labels. It is clear that quasistatic balance between the gravitational force and the contact wrench cone can only occur for the tipping without slipping contact mode $f b s_r$. Therefore, the only quasistatic solution is that the block begins to tip without sliding, and the speed of this motion is determined by the speed of the finger's motion. The graphical construction can be used to confirm our intuition that tipping of the block occurs if we push high on the block or if the friction coefficient at the block's support is high. Try it by pushing a can or

Fig. 37.9 (a) A part supported by a horizontally vibrating surface. (b) Friction between the part and the surface causes the part to always try to catch up to the surface, but its acceleration is bounded by $\pm\mu g$. The asymmetric motion of the surface gives the part an average positive velocity over a cycle

glass. Quasistatically, the height of the center of mass is immaterial.

A final example is given in Fig. 37.9. A part of mass m and friction coefficient μ is supported by a horizontal surface that moves periodically in the horizontal direction. The periodic motion consists of a large negative acceleration for a short duration and a smaller positive acceleration for a longer duration. The horizontal friction force that can be applied to the part is bounded by $\pm\mu mg$, so the part's horizontal acceleration is bounded by $\pm\mu g$. As a result, the part cannot keep up with the surface as it accelerates backward. Instead, the part slips forward with respect to the surface, which means that the maximal friction force acts in the negative direction, and the part attempts to slow down to the surface's velocity. Eventually the part catches up to the surface as it executes its slow forward acceleration, which is less than μg . Once the part catches up to the surface, it sticks to it, until the next backward acceleration phase. As is evident in Fig. 37.9, the average part velocity over a cycle is positive, so the part moves forward on the surface [37.52, 53]. This idea can be extended to create a wide variety of frictional force fields on a rigid plate vibrated with three degrees of freedom in a horizontal plane [37.54, 55] or with a full six degrees of freedom [37.56].

For further examples of manipulation planning using the rigid-body model with Coulomb friction, see [37.14] and the references therein.

37.5 Pushing Manipulation

The friction limit surface (Sect. 37.7) is useful for analyzing pushing manipulation, as it describes the friction forces that can occur as a part slides over a support surface. When the part is pushed with a wrench contained within the limit surface, friction between the part and the support resists the pushing wrench and the part remains motionless. When the part slides quasistatically, the pushing wrench w lies on the limit surface, and the part's twist t is normal to the limit surface at w (Fig. 37.10). When the part translates without rotating, the friction force magnitude is μmg , where m is the part's mass and g is gravitational acceleration. The force applied by the part to the surface is directed through the part's center of mass in the direction of translation.

If the pushing wrench makes positive moment about the part's center of mass, the part will rotate counter-clockwise (CCW), and if it makes negative moment about the part's center of mass, it will rotate clockwise (CW). Similarly, if the contact point on the part moves along a line that passes around the part's center of mass in a CW (respectively, CCW) sense, then the part will rotate CW (CCW). From these two observations and considering all possible contact modes, we can conclude that a part pushed at a point contact will rotate CW (CCW) if either (1) both edges of the contact friction cone pass CW (CCW) about the cen-

ter of mass, or (2) one edge of the friction cone and the pushing direction at the contact both pass around the center of mass in a CW (CCW) sense [37.14, 57], (Fig. 37.11).

This observation allows pushing to be used to reduce uncertainty in part orientation. A series of pushes with a flat fence can be used to completely eliminate the uncertainty in the orientation of a polygonal part [37.57–59]. Bounds on the rate of rotation of parts [37.14, 60, 61] allow the use of a sequence of stationary fences suspended above a conveyor belt to orient parts by pushing them as they are carried along by the conveyor [37.62, 63]. *Stable* pushing plans (Fig. 37.12) use pushing motions that are guaranteed to keep the part fixed to the pusher as it moves, even

Fig. 37.10 (a) Contact between a pusher and a sliding object. (b) The composite contact wrench cone. (c) Mapping the wrench cone through the limit surface to twists of the object. (d) The unit twists that can result from forces in the composite wrench cone

Fig. 37.11 The pusher's motion direction votes for counter-clockwise rotation of the part, but it is outvoted by the two edges of the friction cone, which both indicate clockwise rotation

Fig. 37.12 Stable pushes can be used to maneuver a part among obstacles

in the face of uncertainty in the part's pressure distribution [37.14, 64, 65]. Extensions of this work find pushing motions for planar assemblies of parts so that they remain fixed in their relative configurations during motion [37.66–68].

The examples above assume that pushing forces and support friction forces act in the same plane. Other work on pushing has considered three-dimensional effects, where pushing forces are applied above the support plane [37.69].

37.6 Contact Interfaces and Modeling

Contact interface is a general expression to describe the kinematics and kinetics of contacts. Contact applies in various contexts in robotics research; thus, it is more meaningful to refer to generic contact as an *interface*, which is not limited to fingers in grasping and manipulation. The concept of *contact interface* extends the traditional context of physical *contact*. It refers to an interface which imparts kinematic filtering as well as the duality of force/motion transmitted across the contact interface.

Consequently, a contact interface, whether it is rigid or deformable, can be considered as a *kinematic filter* which includes two characteristics: (a) motion and force transmission, and (b) kinematic duality between force/moment and motion. Different contact interfaces will be described in the following sections.

Previous sections of this chapter have assumed rigid bodies in contact. In reality, however, all contacts are accompanied by some deformation of the objects. Often this is by design, as in the case of compliant robot fingertips. When deformation is non-negligible, elastic contact models can be used.

37.6.1 Modeling of Contact Interface

Contact modeling depends on the nature of bodies in contact, including their material properties, applied force, contact deformation, and elastic properties. This section discusses different contact models.

Rigid-Body and Point-Contact Models

With the rigid-body assumption, as discussed in the previous sections of this chapter, two models are often used: (a) *point contact without friction* and (b) *point contact with friction*. In the former case, the contact can only apply force in the direction normal to the contact. In the latter case, a tangential friction force is applied in addition to the normal force. The simplest analytical model for point contact with friction is the Coulomb friction model as presented in (37.9).

Hertzian Contact Model

Elastic contact modeling was first studied and formulated more than a century ago by *Hertz* in 1882 [37.70]

based on contact between two linear elastic materials with a normal force which results in very small contact deformation. This is commonly called the *Hertzian* contact and can be found in most mechanics textbooks, such as [37.71, 72]. Hertz made two important explicit assumptions in order for his contact model to be applicable:

1. Objects of linear elastic materials in contact,
2. Small contact deformation compared to the dimension of object.

Hertz also conducted experiments using a spherical glass lens against a planar glass plate to validate the contact theory.

Two relevant results of the Hertzian contact theory applied to robotic contact interfaces are summarized as follows. The first pertains to the radius of the contact area. *Hertz* [37.70] studied the growth of the contact area as a function of the applied normal force N based on the linear elastic model. Based on ten experimental trials, he concluded that the radius of contact is proportional to the normal force raised to the power of $1/3$, which is consistent with the analytical results he derived based on the linear elastic model. That is, the radius of contact, a , is related to the normal force, N , by

$$a \propto N^{1/3}. \quad (37.15)$$

The second result pertains to the pressure distribution over the assumed symmetric contact area – a second-order pressure distribution of the nature of an ellipse or circle. For a symmetric and circular contact area, the pressure distribution is

$$p(r) = \frac{N}{\pi a^2} \sqrt{1 - \left(\frac{r}{a}\right)^2}, \quad (37.16)$$

where N is the normal force, a is the radius of contact, and r is the distance from the center of contact with $0 \leq r \leq a$.

Soft Contact Model. A typical contact interface between a soft finger and contact surface is illustrated in Fig. 37.13. In typical robotic contact interfaces, the materials of the fingertips are not linear elastic. A model

that extends linear to nonlinear elastic contact was presented in [37.38] with a power-law equation which subsumes the Hertzian contact theory,

$$a = c N^\gamma, \quad (37.17)$$

where $\gamma = n/(2n+1)$ is the exponent of the normal force, n is the strain-hardening exponent, and c is a constant depending on the size and curvature of the fingertip as well as the material properties. Equation (37.17) is the new power law that relates the growth of the circular contact radius to the applied normal force for soft fingers. Note that the equation is derived assuming circular contact area. For linear elastic materials, the constant n is equal to 1 with $\gamma = 1/3$, resulting in the Hertzian contact model in (37.15). Therefore, the soft contact model in (37.17) subsumes the Hertzian contact model.

Viscoelastic Soft Contact Model. Typical soft materials used in robotic fingertip, e.g., rubber, silicone and polymers, show viscoelastic properties. Viscoelasticity is a physical phenomenon of time-dependent strain and stress [37.73]. Specifically in the context of robotic grasping and manipulation, there are two types of time dependent responses [37.74–76]:

1. *Relaxation*: The evolution of force in grasping while the displacement is held constant;
2. *Creep*: The evolution of displacement in contact and grasping while the external force is held constant.

Such time-dependent responses would approach equilibrium asymptotically. Viscoelastic materials also exhibit the properties of:

1. *Strain history dependence*: The response of the material depends on prior strain history; and
2. *Energy dissipation*: A net energy dissipation associated with a complete cycle of loading and unloading.

Fig. 37.13 An elastic soft fingertip with a hemispherical tip making contact with a rigid surface

Two popular viscoelastic models include: the Kelvin–Voigt/Maxwell model (the spring-damper model) and the Fung’s model, which will be described in the following.

(1) **Kelvin–Voigt/Maxwell model.** The Kelvin–Voigt’s solid model was constructed by a spring and a damper connected in parallel [37.77] as shown in Fig. 37.14. The relation between the stress, σ , and strain, ϵ , can be formulated as

$$\sigma = k\epsilon + c \frac{d\epsilon}{dt}. \quad (37.18)$$

Maxwell proposed in 1867 the Maxwell fluid model [37.78] as a single set of spring and damper in series as shown in Fig. 37.15. The relationship between the stress, σ , and strain, ϵ , can be expressed as

$$\frac{1}{k} \frac{d\sigma}{dt} + \frac{\sigma}{c} = \frac{d\epsilon}{dt}. \quad (37.19)$$

The *generalized Maxwell model* utilizes multiple serial spring-damper sets and a spring connected in parallel. One can employ the curve-fitting techniques using the experimental data to find the modeling parameters of springs and dampers.

However, the issue of this model is often on the lack of consistency of the parameters (stiffness constants and damping factors) obtained from the model. Such parameters can have large discrepancy in numerical values, often in two orders of magnitude or higher, while representing the same material with supposedly similar values of springs and dampers. These parameters sometimes can also present unrealistic difference in scales under different experimental setup (e.g., in [37.79, 80]).

(2) **Fung’s model.** A popular viscoelastic model in modeling biomedical materials is the Fung’s model [37.76], proposed by Fung in 1993. The main idea of the model is to represent the reacting force as the product of two independent responses: the temporal response and the elastic response, while incorporating

Fig. 37.14
Kelvin–Voigt
model

Fig. 37.15
Maxwell model

the history of the stress response. The model may be written as

$$T(t) = \int_{-\infty}^t G(t-\tau) \frac{\partial T^{(e)}[\lambda(t)]}{\partial \lambda} \frac{\partial \lambda(\tau)}{\partial \tau} d\tau, \quad (37.20)$$

where $T(t)$ is the tensile stress at time t , with a step increase of size λ in elongation on the specimen, the function $T^{(e)}(\lambda)$ is the so-called elastic response, and $G(t)$, a normalized function of time, is the reduced relaxation function.

Tiezzi and Kao [37.42, 81, 82] simplified this model to study the soft contact interface by assuming no past stress history, as expressed in (37.21)

$$G(\delta, t) = N^{(e)}(\delta) \cdot g(t), \quad (37.21)$$

where $G(\delta, t)$ represents the grasping force as a function of the displacement δ and time t , $N^{(e)}(\delta)$ represents the elastic response of normal force as a function of the displacement (or depression unto the object), and $g(t)$ represents the temporal response of relaxation or creep. The important property of this model is the separation of the spatial response and temporal response as two independent functions. It was shown that the viscoelastic model has an important implication on the stability of grasping which cannot be captured by rigid or linear elastic modeling.

Other Models. In addition to the aforementioned models, other models from different viewpoints were proposed, as follows: From the viewpoint of rheological perspectives [37.83–86]; molecular perspectives [37.73, 87–92]; energy perspectives [37.85]; distributed modeling perspectives [37.93–98] and stress wave propagation perspectives [37.99–102].

37.6.2 Pressure Distribution at Contacts

In Sect. 37.6.1, when the Hertzian contact theory is considered, the assumed pressure distribution for small elastic deformation is given in (37.16). As the radius of curvature of the two asperities increases and the material properties change to hyperelastic, the pressure distribution becomes more uniform [37.38, 103, 104]. Generalizing equation (37.16), the pressure distribution function for circular contact area with radius a is

$$p(r) = C_k \frac{N}{\pi a^2} \left[1 - \left(\frac{r}{a} \right)^k \right]^{\frac{1}{k}}, \quad (37.22)$$

where N is the normal force, a is the radius of contact, r is the radius with $0 \leq r \leq a$, k determines the shape of the pressure profile, and C_k is a coefficient that adjusts for the profile of pressure distribution over the contact area to satisfy the equilibrium condition. In (37.22), $p(r)$ is defined for $0 \leq r \leq a$. By symmetry, $p(r) = p(-r)$ when $-a \leq r \leq 0$, as shown in Fig. 37.16. When k becomes larger, the pressure distribution approaches uniform distribution, as shown in Fig. 37.16. It is also required that the integral of the pressure over the contact area be equal to the normal force; that is

$$\int_R p(r) dA = \int_{\theta=0}^{2\pi} \int_{r=0}^a p(r) r dr d\theta = N. \quad (37.23)$$

The coefficient C_k can be obtained by substituting (37.22) into (37.23). It is interesting to note that when (37.23) is integrated, both the normal force and radius of contact vanish, leaving only the constant C_k as follows

$$C_k = \frac{3}{2} \frac{k \Gamma(\frac{3}{k})}{\Gamma(\frac{1}{k}) \Gamma(\frac{2}{k})}, \quad (37.24)$$

Fig. 37.16 Illustration of pressure distribution with respect to the normalized radius, r/a . The plot shows an axisymmetric pressure distribution with $k = 2, 3, 4, 5$, and ∞ . As k increases, the pressure profile becomes more uniform

where $k = 1, 2, 3, \dots$ are typically integer values (although noninteger k values are also possible) and $\Gamma()$ is the gamma function [37.105]. The numerical values of C_k for a few values of k are listed in Table 37.2 for reference. A normalized pressure distribution with respect to the normalized radius, r/a , is plotted in Fig. 37.16. As can be seen from the figure, when k approaches infinity, the pressure profile will become that of a uniformly distributed load with magnitude of $N/(\pi a^2)$, in which case $C_k = 1.0$.

For linear elastic materials, $k = 2$ can be used, although it is found that $k \cong 1.8$ is also appro-

Table 37.2 Values of the coefficient C_k in the pressure distribution (37.22)

k	Coefficient C_k
$k = 2$ (circular)	$C_2 = 1.5$
$k = 3$ (cubic)	$C_3 = 1.24$
$k = 4$ (quadruple)	$C_4 = 1.1441$
$k \rightarrow \infty$ (uniform)	$C_\infty = 1.0$

priate in some cases [37.106]. For nonlinear elastic and viscoelastic materials, the value of k tends to be higher, depending on the properties of the material.

37.7 Friction Limit Surface

Section 37.3 introduced the notion of a wrench cone, describing the set of wrenches that can be applied through a point contact with friction. Any contact wrench is limited to lie within the surface of the cone. This gives rise to the general notion of a *friction limit surface* – the surface bounding the set of wrenches that can be applied through a given contact or set of contacts.

In this section we study the particular case of limit surfaces arising from planar contact patches [37.7, 107]. A planar contact patch occurs when a flat object slides on the floor, a soft robot finger presses against a face of a polyhedron, or a foot of a humanoid robot pushes on the ground. We would like to know what wrenches can be transmitted through such a contact. In the rest of this section, we focus on the properties of the limit surface of a planar contact patch with a specified pressure distribution over the patch.

For ease of discussion, we will call one of the objects in contact the *part* (e.g., the flat object on the floor or the robot finger) and the other object a stationary *support*. We define a coordinate frame so that the planar contact patch is in the $z = 0$ plane, and let $p(\mathbf{r}) \geq 0$ be the contact pressure distribution between the part and support as a function of the location $\mathbf{r} = (x, y)^T$. The friction coefficient at the contact patch is μ . If the planar velocity of the part is $\mathbf{t} = (\omega_z, v_x, v_y)^T$, then the linear velocity at \mathbf{r} is

$$\mathbf{v}(\mathbf{r}) = (v_x - \omega_z y, v_y + \omega_z x)^T,$$

and the unit velocity is $\hat{\mathbf{v}}(\mathbf{r}) = \mathbf{v}(\mathbf{r})/\|\mathbf{v}(\mathbf{r})\|$. The infinitesimal force applied by the part to the support at \mathbf{r} , in the plane of sliding, is

$$d\mathbf{f}(\mathbf{r}) = [df_x(\mathbf{r}), df_y(\mathbf{r})]^T = \mu p(\mathbf{r}) \hat{\mathbf{v}}(\mathbf{r}). \quad (37.25)$$

The total wrench the part applies to the support is

$$\begin{aligned} \mathbf{w} &= \begin{pmatrix} m_z \\ f_x \\ f_y \end{pmatrix} \\ &= \int_A \begin{pmatrix} x df_y(\mathbf{r}) - y df_x(\mathbf{r}) \\ df_x(\mathbf{r}) \\ df_y(\mathbf{r}) \end{pmatrix} dA, \end{aligned} \quad (37.26)$$

where A is the support area.

As expected, the wrench is independent of the speed of motion: for a given \mathbf{t}_0 and all $\alpha > 0$, the wrench resulting from velocities $\alpha \mathbf{t}_0$ is identical. Viewing (37.26) as a mapping from twists to wrenches, we can map the surface of the unit twist sphere ($\|\hat{\mathbf{t}}\| = 1$) to a surface in the wrench space. This surface is the limit surface, and it is closed, convex, and encloses the origin of the wrench space (Fig. 37.17). The portion of the wrench

Fig. 37.17 Contact and coordinates for COR and local infinitesimal area dA for numerical integration to construct the limit surface of soft fingers

space enclosed by this surface is exactly the set of wrenches the part can transmit to the support. When the part slips on the support ($\mathbf{t} \neq 0$), the contact wrench \mathbf{w} lies on the limit surface, and by the maximum-work inequality, the twist \mathbf{t} is normal to the limit surface at \mathbf{w} . If the pressure distribution $p(\mathbf{r})$ is finite everywhere, the limit surface is smooth and strictly convex, and the mapping from unit twists to unit wrenches, and vice versa, is continuous and one-to-one. The limit surface also satisfies the property $\mathbf{w}(-\hat{\mathbf{t}}) = -\mathbf{w}(\hat{\mathbf{t}})$.

37.7.1 The Friction Limit Surface at a Soft Contact Interface

Given a pressure distribution in (37.22) we can numerically construct the corresponding friction limit surface by using (37.25) and (37.26). For an infinitesimal contact area, the contact resembles a point contact. Hence, the Coulomb's law of friction can be employed.

In the following, we will exploit the kinematic property of center of rotation (COR) with modeling symmetry to formulate equations for the magnitudes of friction force and moment on a circular contact patch. Figure 37.17 shows a circular contact patch with an instantaneous COR. By moving (or scanning) the COR along the x -axis, different possible combinations of friction force and moment can be obtained to construct the limit surface. More details can be found in [37.35–38, 41, 41, 42, 107–109].

The following derivation is for the total friction force (f_t) and moment (m_z) on the contact interface for the COR at a distance d_c along the x -axis, as shown in Fig. 37.17. By varying the COR distance d_c from $-\infty$ to ∞ , all possible combinations of (f_t, m_z) can be found in order to construct the entire friction limit surface.

The tangential force over the entire contact area can be obtained by integrating shear force on each infinitesimal areas, dA , on which the Coulomb's law of friction is observed, over the entire contact area, A . When Hertzian contact pressure distribution [37.70] is considered, use $k = 2$ in (37.22). Setting $\mathbf{r} = (x, y)^T$ and $r = \|\mathbf{r}\|$, the total tangential force can be integrated using (37.25) to obtain

$$\mathbf{f}_t = \begin{pmatrix} f_x \\ f_y \end{pmatrix} = - \int_A \mu \hat{\mathbf{v}}(\mathbf{r}) p(r) dA, \quad (37.27)$$

where A denotes the circular contact region in Fig. 37.17, \mathbf{f}_t is the tangential force vector with the direction shown in Fig. 37.17, μ is the coefficient of friction, $\hat{\mathbf{v}}(\mathbf{r})$ is the unit vector in the direction of the velocity vector $\mathbf{v}(\mathbf{r})$ with respect to the COR on the infinitesimal area dA at the location \mathbf{r} , and $p(r)$ is the pressure distribution at distance r from the center of

contact. Since the pressure along the annular ring with distance r from the center is the same, we denote it by $p(r)$ instead of $p(\mathbf{r})$. The minus sign denotes the opposite directions of $\hat{\mathbf{v}}(\mathbf{r})$ and \mathbf{f}_t . Since we are primarily interested in the magnitude of the friction force and moment, we shall omit this sign in the later derivation when magnitudes are concerned.

Similarly, the moment about the z -axis, or the normal to the contact area, is

$$m_z = \int_A \mu \|\mathbf{r} \times \hat{\mathbf{v}}(\mathbf{r})\| p(r) dA, \quad (37.28)$$

where $\|\mathbf{r} \times \hat{\mathbf{v}}(\mathbf{r})\|$ is the magnitude of the cross product of the vectors \mathbf{r} and $\hat{\mathbf{v}}(\mathbf{r})$, whose direction is normal to the contact surface.

The unit vector $\hat{\mathbf{v}}(\mathbf{r})$ is related to the distance d_c from the origin to the COR chosen on the x -axis from Fig. 37.17, and can be written as follows

$$\begin{aligned} \hat{\mathbf{v}}(\mathbf{r}) &= \frac{1}{\sqrt{(x-d_c)^2 + y^2}} \begin{bmatrix} -y \\ (x-d_c) \end{bmatrix} \\ &= \frac{1}{\sqrt{(r \cos \theta - d_c)^2 + (r \sin \theta)^2}} \\ &\quad \times \begin{bmatrix} -r \sin \theta \\ (r \cos \theta - d_c) \end{bmatrix}. \end{aligned} \quad (37.29)$$

Due to symmetry, $f_x = 0$ for all CORs along the x -axis; therefore, the magnitude of the tangential force in the contact tangent plane is $f_t = f_y$. Substituting equations (37.22) and (37.29) into (37.27) and (37.28), we obtain

$$\begin{aligned} f_t &= \int_A \mu \frac{(r \cos \theta - d_c)}{\sqrt{r^2 + d_c^2 - 2rd_c \cos \theta}} C_k \\ &\quad \times \frac{N}{\pi a^2} \left[1 - \left(\frac{r}{a} \right)^k \right]^{\frac{1}{k}} dA. \end{aligned} \quad (37.30)$$

Similarly, the moment about the axis normal to the plane is

$$\begin{aligned} m_z &= \int_A \mu \frac{r^2 - r d_c \cos \theta}{\sqrt{r^2 + d_c^2 - 2rd_c \cos \theta}} C_k \\ &\quad \times \frac{N}{\pi a^2} \left[1 - \left(\frac{r}{a} \right)^k \right]^{\frac{1}{k}} dA. \end{aligned} \quad (37.31)$$

In (37.30) and (37.31), polar coordinates are defined such that $x = r \cos \theta$, $y = r \sin \theta$, and $dA = r dr d\theta$. We also introduce a normalized coordinate

$$\tilde{r} = \frac{r}{a}. \quad (37.32)$$

From (37.32), we can write $dr = a d\tilde{r}$. We also denote $\tilde{d}_c = d_c/a$, and assume that μ is constant throughout the contact area. Substituting the normalized coordinate into equation (37.30) and dividing both sides by μN , we can derive

$$\frac{f_t}{\mu N} = \frac{C_k}{\pi} \int_0^{2\pi} \int_0^1 \frac{(\tilde{r}^2 \cos \theta - \tilde{r} \tilde{d}_c)}{\sqrt{\tilde{r}^2 + \tilde{d}_c^2 - 2\tilde{r} \tilde{d}_c \cos \theta}} \times (1 - \tilde{r}^k)^{\frac{1}{k}} d\tilde{r} d\theta. \quad (37.33)$$

Substituting again $\tilde{r} = r/a$ and $dr = a d\tilde{r}$ into (37.31) and normalizing with $a\mu N$, we obtain

$$\frac{m_z}{a\mu N} = \frac{C_k}{\pi} \int_0^{2\pi} \int_0^1 \frac{(\tilde{r}^3 \cos \theta - \tilde{r}^2 \tilde{d}_c)}{\sqrt{\tilde{r}^2 + \tilde{d}_c^2 - 2\tilde{r} \tilde{d}_c \cos \theta}} \times (1 - \tilde{r}^k)^{\frac{1}{k}} d\tilde{r} d\theta. \quad (37.34)$$

Equations (37.33) and (37.34) can be numerically integrated for a distance d_c or \tilde{d}_c to yield a point on the limit surface for a prescribed pressure distribution $p(r)$ given by (37.22). Both equations involve elliptic integrals whose closed-form solutions may not exist but can be evaluated numerically. When the COR distance d_c varies from $-\infty$ to ∞ , all possible combinations of (f_t, m_z) can be obtained for plotting the friction limit surface.

Fig. 37.18 Example limit surface obtained by numerical integration and elliptical approximation. The numerical integration is based on the pressure distribution, $p(r)$, and the coefficient, C_k . In this figure, the pressure distributions in (37.22) of both $k=2$ and $k=4$ are used

37.7.2 Example of Constructing a Friction Limit Surface

When the pressure distribution is fourth order with $k=4$, the coefficient from Table 37.2 is $C_4 = (6/\sqrt{\pi})(\Gamma(3/4)/\Gamma(1/4)) = 1.1441$. Equations (37.33) and (37.34) can be written as

$$\frac{f_t}{\mu N} = 0.3642 \int_0^{2\pi} \int_0^1 \frac{(\tilde{r}^2 \cos \theta - \tilde{r} \tilde{d}_c)}{\sqrt{\tilde{r}^2 + \tilde{d}_c^2 - 2\tilde{r} \tilde{d}_c \cos \theta}} \times (1 - \tilde{r}^4)^{\frac{1}{4}} d\tilde{r} d\theta.$$

$$\frac{m_z}{a\mu N} = 0.3642 \int_0^{2\pi} \int_0^1 \frac{(\tilde{r}^3 \cos \theta - \tilde{r}^2 \tilde{d}_c)}{\sqrt{\tilde{r}^2 + \tilde{d}_c^2 - 2\tilde{r} \tilde{d}_c \cos \theta}} \times (1 - \tilde{r}^4)^{\frac{1}{4}} d\tilde{r} d\theta.$$

Numerical integration for different values of \tilde{d}_c yields pairs of $(f_t/(\mu N), m_z/(a\mu N))$. Plots of these pairs are shown in Fig. 37.18.

A reasonable approximation to these numerical results is given by the following equation of an ellipse

$$\left(\frac{f_t}{\mu N}\right)^2 + \left(\frac{m_z}{(m_z)_{\max}}\right)^2 = 1, \quad (37.35)$$

where the maximum moment $(m_z)_{\max}$ is

$$(m_z)_{\max} = \int_A \mu |r| C_k \frac{N}{\pi a^2} \left[1 - \left(\frac{r}{a}\right)^k\right]^{\frac{1}{k}} dA, \quad (37.36)$$

Fig. 37.19a,b Friction limit surface for soft fingers: (a) a 3-D ellipsoid representing the limit surface, and (b) a section of the ellipsoidal limit surface showing the coupled relationship between the force and moment, as those obtained in Fig. 37.18

obtained by (37.31) with the COR at $d_c = 0$. This defines the quarter-elliptical curves in Fig. 37.18. This approximation is the basis for constructing a three-dimensional (3-D) ellipsoidal limit surface, as illus-

trated in Fig. 37.19, and is a good model for the soft contact described in Sect. 37.6.1. More details can be found in [37.35–37, 39–42].

37.8 Contacts in Grasping and Fixture Designs

It is often important to relate the force and contact displacement (or deformation of contact interface) in grasping and fixture design in which deformable contacts are concerned. Furthermore, such a force–displacement relationship is typically nonlinear due to the nature of contact. A linear expression such as Hooke's law cannot capture the instantaneous and overall characteristics of force and displacement for these contacts. In this section, we formulate and discuss such a relationship using the elastic contact model.

From Fig. 37.13 and the geometry of contact, (37.17), relating the contact radius with normal force, can be rewritten. Assuming $d \ll R_0$, the following equation can be derived [37.39]

$$N = c_d d^\zeta, \quad (37.37)$$

where c_d is a proportional constant, and ζ is

$$\zeta = \frac{1}{2\gamma}. \quad (37.38)$$

Both c_d and ζ can be obtained experimentally. The exponent ζ can also be obtained from γ through (37.38)

Fig. 37.20 The typical load–depression curve in (37.37) shown with a scale to the right, and the contact stiffness, k_s , as given by (37.39) with a scale to the left

if γ is already known for the fingertip. The range of the exponent in (37.37) is $3/2 \leq \zeta < \infty$. In (37.37), the approach or the vertical depression of the fingertip, d , is proportional to the normal force raised to the power of 2γ (cf. (37.38)) which ranges from 0 to $2/3$.

A plot of normal force versus displacement of contact is shown in Fig. 37.20 using (37.37) with a nonlinear power-law equation. Experimental data of contact between a soft finger and flat surface show consistent results when compared with Fig. 37.20 [37.39].

37.8.1 Contact Stiffness of Soft Fingers

The nonlinear contact stiffness of a soft finger is defined as the ratio of the change in normal force with respect to the change in vertical depression at the contact. The contact stiffness of soft fingers can be obtained by differentiating (37.37) as follows

$$k_s = \frac{\partial N}{\partial d} = c_d \zeta d^{\zeta-1} = \zeta \left(\frac{N}{d} \right). \quad (37.39)$$

Substitute (37.37) with $d = \left(\frac{N}{c_d} \right)^{1/\zeta}$ into (37.39) to derive

$$k_s = c_d^{\frac{1}{\zeta}} \zeta N^{\frac{\zeta-1}{\zeta}} = c_d^{2\gamma} \zeta N^{1-2\gamma}. \quad (37.40)$$

Thus, the nonlinear contact stiffness of soft fingers, derived in a succinct form in (37.39), is the product of the exponent ζ and the ratio of the normal force versus the approach, N/d . A typical contact stiffness as a function of vertical depression is plotted in Fig. 37.20. The stiffness shown in the figure increases with the force. The expressions for the stiffness, k_s , as a function of various parameter(s) are summarized in the following Table 37.3.

Table 37.3 Summary of equations of contact stiffness

	$f(d)$	$f(N)$	$f(N, d)$
k_s	$c_d \zeta d^{\zeta-1}$	$c_d^{\frac{1}{\zeta}} \zeta N^{\frac{\zeta-1}{\zeta}}$	$\zeta \left(\frac{N}{d} \right)$

Table 37.4 Summary of the contact mechanics equations for linear elastic (when $\gamma = 1/3$ or $\zeta = 3/2$) and nonlinear elastic soft fingers

Description	Equation for soft fingers	Parameters
Power law	$a = cN^\gamma$	$0 \leq \gamma \leq \frac{1}{3}$
Pressure distribution	$p(r) = p(0) \left[1 - \left(\frac{r}{a} \right)^k \right]^{\frac{1}{k}}$	Typically $k \geq 1.8$
Contact approach	$N = c_d d^\zeta$	$\frac{3}{2} \leq \zeta \leq \infty$
Contact stiffness	$k_s = \zeta \frac{N}{d}$	Nonlinear

The change in stiffness can be obtained by differentiating (37.39) to derive the following equations

$$\frac{\partial k_s}{\partial d} = c_d \zeta (\zeta - 1) d^{\zeta-2}, \tag{37.41}$$

$$\frac{\partial k_s}{\partial N} = \frac{\zeta - 1}{d}. \tag{37.42}$$

Equation (37.39) suggests that the stiffness of soft contacts always increases because the ratio N/d always increases, with constant ζ for prescribed fingertip material and range of normal force. This is consistent with the observation that the contact stiffness becomes larger (i. e., stiffer) with larger depression and force. Additionally, (37.42) suggests that the contact stiffness k_s always increases with the normal force because $\partial k_s / \partial N > 0$ owing to $\zeta \geq 1.5$. Moreover, the change in stiffness with respect to the normal load is inversely proportional to the vertical depression, d , as derived in (37.42). This result asserts that the rate of increase in the contact stiffness will gradually become less and less as the normal load and vertical depression increase.

A summary of the equations for soft fingers is presented in Table 37.4. The range of the exponent of

the general power-law equation in (37.17) is $0 \leq \gamma \leq 1/3$. The Hertzian contact has an exponent of $\gamma = 1/3$; therefore, the Hertzian contact theory for linear elastic materials, such as steel or other metallic fingertips, under small deformation, generally follow the Hertzian contact theory fairly well. The power-law equation in (37.17) should be employed for fingertips made of softer materials, such as soft rubber or silicone or even viscoelastic fingertips.

37.8.2 Application of Soft Contact Theory to Fixture Design

The preceding analysis and results can be applied in fixturing design and other applications that involve contact with finite areas [37.6]. In fixture design with soft contacts (e.g., copper surfaces) under relatively large deformation and load, the power-law equations in Table 37.4 should be considered in place of the Hertzian contact equation. In these cases, the Hertzian contact model is no longer accurate and should be replaced. On the other hand, if linear elastic materials are used in fixture design with relatively small deformation ($d/R_0 \leq 5\%$), the exponent should be taken as $\gamma = 1/3$ when applying the contact theory. Furthermore, the exponent γ was found to be material dependent and not geometry dependent in general [37.38]. Once the value of γ is determined for the material (for example, using a tensile testing machine with the experimental procedure in [37.38]), it can be employed for the analysis of fixturing design using the relevant equations presented herewith.

37.9 Conclusions and Further Reading

In this chapter, both rigid-body and elastic models of contact interfaces are discussed, including kinematic constraints and the duality between the contact wrenches and twists. Contact forces that may arise with Coulomb friction are described. Multiple-contact manipulation tasks with rigid-body and Coulomb friction are presented. Soft and viscoelastic contact interfaces are presented and discussed. The friction limit surface is introduced and utilized to analyze pushing problems. An example of constructing a friction limit surface for soft contact is presented based on the formulation of force/moment of soft contact interface. Applications of these contact models in fixture analysis and design are presented with the modeling of

contact interface. Many references in the bibliography section of this chapter provide further reading on this subject.

Manipulation modes include grasping, pushing, rolling, batting, throwing, catching, casting, and other kinds of quasistatic and dynamic manipulation [37.110]. This chapter presents an overview of contact modeling interfaces, with a particular focus on their use in manipulation tasks, including graspless or *nonprehensile* manipulation modes such as pushing. Analyses of grasps and fixtures are also presented. *Mason's* textbook [37.14] expands on a number of themes in this chapter, including the theory of polyhedral convex cones, graphical methods for planar problems, and

applications to manipulation planning. Fundamental material on polyhedral cones can be found in [37.111] and their application to representations of twists and wrenches in [37.10, 112–114]. Twists and wrenches are elements of classical *screw theory*, which is covered in

the texts [37.115, 116] and from the point of view of robotics in the texts [37.30, 117, 118].

In addition, several relevant chapters in this handbook provide further reading for theory and applications, for example, Chaps. 2 and 38.

38. Grasping

Domenico Prattichizzo, Jeffrey C. Trinkle

This chapter introduces fundamental models of grasp analysis. The overall model is a coupling of models that define contact behavior with widely used models of rigid-body kinematics and dynamics. The contact model essentially boils down to the selection of components of contact force and moment that are transmitted through each contact. Mathematical properties of the complete model naturally give rise to five primary grasp types whose physical interpretations provide insight for grasp and manipulation planning.

After introducing the basic models and types of grasps, this chapter focuses on the most important grasp characteristic: complete restraint. A grasp with complete restraint prevents loss of contact and thus is very secure. Two primary restraint properties are *form closure* and *force closure*. A form closure grasp guarantees maintenance of contact as long as the links of the hand and the object are well-approximated as rigid and as long as the joint actuators are sufficiently strong. As will be seen, the primary difference between form closure and force closure grasps is the latter's reliance on contact friction. This translates into requiring fewer contacts to achieve force closure than form closure.

The goal of this chapter is to give a thorough understanding of the all-important grasp properties of form and force closure. This will be done through detailed derivations of grasp models and

discussions of illustrative examples. For an in-depth historical perspective and a treasure-trove bibliography of papers addressing a wide range of topics in grasping, the reader is referred to [38.1].

Mechanical hands were developed to give robots the ability to grasp objects of varying geometric and physical properties. The first robotic hand designed for dexterous manipulation was the Salisbury Hand (Fig. 38.1) [38.2]. It has three three-jointed fingers;

enough to control all six degrees of freedom of an object and the grip pressure. The fundamental grasp modeling and analysis done by Salisbury provides a basis for grasp synthesis and dexterous manipulation research which continues today. Some of the most ma-

ture analysis techniques are embedded in the widely used software *GraspIt!* [38.3] and *SynGrasp* [38.4, 5]. *GraspIt!* contains models for several robot hands and provides tools for grasp selection, dynamic grasp simulation, and visualization. *SynGrasp* is a MATLAB Toolbox that can be obtained from [38.6] and provides models and functions for grasp analysis with both fully and underactuated hands. It can be a useful educational tool to get acquainted with the mathemat-

ical framework of robotic grasping described in this Chapter. Over the years since the Salisbury Hand was built, many articulated robot hands have been developed. Nearly all of these have one actuator per joint or fewer. A notable exception is the *DLR hand arm system* developed by DLR (Deutsches Zentrum für Luft- und Raumfahrt), which has two actuators per joint that drive each joint independently with two antagonistic tendons (Fig. 38.7) [38.7].

38.1 Models and Definitions

A mathematical model of grasping must be capable of predicting the behavior of the hand and object under various loading conditions that may arise during grasping. Generally, the most desirable behavior is grasp maintenance in the face of unknown disturbing forces and moments applied to the object. Typically these disturbances arise from inertia forces which become appreciable during high-speed manipulation or applied forces such as those due to gravity. Grasp maintenance means that the contact forces applied by the hand are such that they prevent contact separation and unwanted contact sliding. The special class of grasps that can be maintained for every possible disturbing load is known as closure grasps. Figure 38.1 shows the Salisbury Hand [38.2, 8], executing a closure grasp of an object by wrapping its fingers around it and pressing it against its palm. Formal definitions, analysis, and computational tests for closure will be presented in Sect. 38.4.

Figure 38.2 illustrates some of the main quantities that will be used to model grasping systems. Assume that the links of the hand and the object are rigid and that there is a unique, well-defined tangent plane at each contact point. Let $\{N\}$ represent a conveniently chosen inertial frame fixed in the workspace. The frame $\{B\}$

is fixed to the object with its origin defined relative to $\{N\}$ by the vector $p \in \mathbb{R}^3$, where \mathbb{R}^3 denotes three-dimensional Euclidean space. A convenient choice for p is the center of mass of the object. The position of contact point i in $\{N\}$ is defined by the vector $c_i \in \mathbb{R}^3$. At contact point i , we define a frame $\{C\}_i$, with axes $\{\hat{n}_i, \hat{t}_i, \hat{o}_i\}$ ($\{C\}_1$ is shown in *exploded* view). The unit vector \hat{n}_i is normal to the contact tangent plane and directed toward the object. The other two unit vectors are orthogonal and lie in the tangent plane of the contact.

Let the joints be numbered from 1 to n_q . Denote by $q = [q_1 \cdots q_{n_q}]^T \in \mathbb{R}^{n_q}$ the vector of joint displacements, where the superscript T indicates matrix transposition. Also, let $\tau = [\tau_1 \cdots \tau_{n_q}]^T \in \mathbb{R}^{n_q}$ represent joint loads (forces in prismatic joints and torques in revolute joints). These loads can result from actuator actions, other applied forces, and inertia forces. They could also arise from interaction at the contacts between the object and hand. However, it will be convenient to sep-

Fig. 38.1 The Salisbury Hand grasping an object

Fig. 38.2 Main quantities for grasp analysis

arate joint loads into two components: those arising from contacts and those arising from all other sources. Throughout this Chapter, non-contact loads will be denoted by τ .

Let $\mathbf{u} \in \mathbb{R}^{n_u}$ denote the vector describing the position and orientation of $\{B\}$ relative to $\{N\}$. For planar systems $n_u = 3$. For spatial systems, n_u is three plus the number of parameters used to represent orientation; typically three (for Euler angles) or four (for unit quaternions). Denote by $\mathbf{v} = [\mathbf{v}^T \boldsymbol{\omega}^T]^T \in \mathbb{R}^{n_v}$, the twist of the object described in $\{N\}$. It is composed of the translational velocity $\mathbf{v} \in \mathbb{R}^3$ of the point \mathbf{p} and the angular velocity $\boldsymbol{\omega} \in \mathbb{R}^3$ of the object, both expressed in $\{N\}$. A twist of a rigid body can be referred to any convenient frame fixed to the body. The components of the referred twist represent the velocity of the origin of the new frame and the angular velocity of the body, both expressed in the new frame (Table 38.1). For a rigorous treatment of twists and wrenches see [38.9, 10]. Note that for planar systems, $\mathbf{v} \in \mathbb{R}^2$, $\boldsymbol{\omega} \in \mathbb{R}$, and so $n_v = 3$.

Another important point is $\dot{\mathbf{u}} \neq \mathbf{v}$. Instead, these variables are related by the matrix \mathbf{V} as

$$\dot{\mathbf{u}} = \mathbf{V}\mathbf{v}, \quad (38.1)$$

where the matrix $\mathbf{V} \in \mathbb{R}^{n_u \times n_v}$ is not generally square, but nonetheless satisfies $\mathbf{V}^T \mathbf{V} = \mathbf{I}$ [38.11], where \mathbf{I} is the identity matrix, and the dot over the \mathbf{u} implies differentiation with respect to time. Note that for planar systems, $\mathbf{V} = \mathbf{I} \in \mathbb{R}^{3 \times 3}$.

Let $\mathbf{f} \in \mathbb{R}^3$ be the force applied to the object at the point \mathbf{p} and let $\mathbf{m} \in \mathbb{R}^3$ be the applied moment. These are combined into the object load, or wrench, vector denoted by $\mathbf{g} = [\mathbf{f}^T \mathbf{m}^T]^T \in \mathbb{R}^{n_v}$, where \mathbf{f} and \mathbf{m} are expressed in $\{N\}$. Like twists, wrenches can be referred to any convenient frame fixed to the body. One can think of this as translating the line of application of the force until it contains the origin of the new frame, then adjusting the moment component of the wrench to offset the moment induced by moving the line of the force. Last, the force and adjusted moment are expressed in the new frame. As done with the joint loads, the object wrench will be partitioned into two main parts: contact and non-contact wrenches. Throughout this chapter, \mathbf{g} will denote the non-contact wrench on the object.

38.1.1 Velocity Kinematics

The material in this chapter is valid for a wide range of robot hands and other grasping mechanisms. The hand is assumed to be composed of a palm that serves as the common base for any number of fingers, each with any number of joints. The formulations given in this chapter are expressed explicitly in terms of only

Table 38.1 Primary notation for grasp analysis

Notation	Definition
n_c	Number of contacts
n_q	Number of joints of the hand
n_v	Number of degrees of freedom of object
n_λ	Number of contact wrench components
$\mathbf{q} \in \mathbb{R}^{n_q}$	Joint displacements
$\dot{\mathbf{q}} \in \mathbb{R}^{n_q}$	Joint velocities
$\boldsymbol{\tau} \in \mathbb{R}^{n_q}$	Non-contact joint loads
$\mathbf{u} \in \mathbb{R}^{n_u}$	Position and orientation of object
$\mathbf{v} \in \mathbb{R}^{n_v}$	Twist of object
$\mathbf{g} \in \mathbb{R}^{n_v}$	Non-contact object wrench
$\boldsymbol{\lambda} \in \mathbb{R}^{n_\lambda}$	Transmitted contact wrenches
$\mathbf{v}_{cc} \in \mathbb{R}^{n_\lambda}$	Transmitted contact twists
$\{B\}$	Frame fixed in object
$\{C\}_i$	Frame at contact i
$\{N\}$	Inertial frame

revolute and prismatic joints. However, most other common joints can be modeled by combinations of revolute and prismatic joints (e.g., cylindrical and planar). Any number of contacts may occur between any link and the object.

Grasp Matrix and Hand Jacobian

Two matrices are of the utmost importance in grasp analysis: the *grasp matrix* \mathbf{G} and the *hand Jacobian* \mathbf{J} . These matrices define the relevant velocity kinematics and force transmission properties of the contacts. The following derivations of \mathbf{G} and \mathbf{J} will be done under the assumption that the system is three-dimensional ($n_v = 6$). Changes for planar systems will be noted later.

Each contact should be considered as two coincident points; one on the hand and one on the object. The hand Jacobian maps the joint velocities to the twists of the hand to the contact frames, while the transpose of the grasp matrix maps the object twist to the contact frames. Finger joint motions induce a rigid body motion in each link of the hand. It is implicit in the terminology, twists of the hand, that the twist referred to contact i is the twist of the link involved in contact i . Thus these matrices can be derived from the transforms that change the reference frame of a twist.

To derive the grasp matrix, let $\boldsymbol{\omega}_{\text{obj}}^N$ denote the angular velocity of the object expressed in $\{N\}$ and let $\mathbf{v}_{i,\text{obj}}^N$, also expressed in $\{N\}$, denote the velocity of the point on the object coincident with the origin of $\{C\}_i$. These velocities can be obtained from the object twist referred to $\{N\}$ as

$$\begin{pmatrix} \mathbf{v}_{i,\text{obj}}^N \\ \boldsymbol{\omega}_{\text{obj}}^N \end{pmatrix} = \mathbf{P}_i^T \mathbf{v}, \quad (38.2)$$

where

$$\mathbf{P}_i = \begin{pmatrix} \mathbf{I}_{3 \times 3} & \mathbf{0} \\ \mathbf{S}(\mathbf{c}_i - \mathbf{p}) & \mathbf{I}_{3 \times 3} \end{pmatrix} \quad (38.3)$$

$\mathbf{I}_{3 \times 3} \in \mathbb{R}^{3 \times 3}$ is the identity matrix, and $\mathbf{S}(\mathbf{c}_i - \mathbf{p})$ is the cross product matrix, that is, given a three-vector $\mathbf{r} = [r_x \ r_y \ r_z]^T$, $\mathbf{S}(\mathbf{r})$ is defined as follows

$$\mathbf{S}(\mathbf{r}) = \begin{pmatrix} 0 & -r_z & r_y \\ r_z & 0 & -r_x \\ -r_y & r_x & 0 \end{pmatrix}.$$

The object twist referred to $\{\mathbf{C}\}_i$ is simply the vector on the left-hand side of (38.2) expressed in $\{\mathbf{C}\}_i$.

Let $\mathbf{R}_i = (\hat{\mathbf{n}}_i \hat{\mathbf{t}}_i \hat{\mathbf{o}}_i) \in \mathbb{R}^{3 \times 3}$ represent the orientation of the i -th contact frame $\{\mathbf{C}\}_i$ with respect to the inertial frame (the unit vectors $\hat{\mathbf{n}}_i$, $\hat{\mathbf{t}}_i$, and $\hat{\mathbf{o}}_i$ are expressed in $\{\mathbf{N}\}$). Then the object twist referred to $\{\mathbf{C}\}_i$ is given as

$$\mathbf{v}_{i,\text{obj}} = \bar{\mathbf{R}}_i^T \begin{pmatrix} \mathbf{v}_{i,\text{obj}}^N \\ \boldsymbol{\omega}_{\text{obj}}^N \end{pmatrix}, \quad (38.4)$$

where $\bar{\mathbf{R}}_i = \text{Blockdiag}(\mathbf{R}_i, \mathbf{R}_i) = \begin{pmatrix} \mathbf{R}_i & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_i \end{pmatrix} \in \mathbb{R}^{6 \times 6}$.

Substituting $\mathbf{P}_i^T \mathbf{v}$ from (38.2) into (38.4) yields the partial grasp matrix $\tilde{\mathbf{G}}_i^T \in \mathbb{R}^{6 \times 6}$, that maps the object twist from $\{\mathbf{N}\}$ to $\{\mathbf{C}\}_i$

$$\mathbf{v}_{i,\text{obj}} = \tilde{\mathbf{G}}_i^T \mathbf{v}, \quad (38.5)$$

where

$$\tilde{\mathbf{G}}_i^T = \bar{\mathbf{R}}_i^T \mathbf{P}_i^T. \quad (38.6)$$

The hand Jacobian can be derived similarly. Let $\boldsymbol{\omega}_{i,\text{hnd}}^N$ be the angular velocity of the link of the hand touching the object at contact i , expressed in $\{\mathbf{N}\}$, and define $\mathbf{v}_{i,\text{hnd}}^N$ as the translational velocity of contact i on the hand, expressed in $\{\mathbf{N}\}$. These velocities are related to the joint velocities through the matrix \mathbf{Z}_i whose columns are the Plücker coordinates of the axes of the joints [38.9, 10]. We have

$$\begin{pmatrix} \mathbf{v}_{i,\text{hnd}}^N \\ \boldsymbol{\omega}_{i,\text{hnd}}^N \end{pmatrix} = \mathbf{Z}_i \dot{\mathbf{q}}, \quad (38.7)$$

where $\mathbf{Z}_i \in \mathbb{R}^{6 \times n_q}$ is defined as

$$\mathbf{Z}_i = \begin{pmatrix} \mathbf{d}_{i,1} & \cdots & \mathbf{d}_{i,n_q} \\ \boldsymbol{\kappa}_{i,1} & \cdots & \boldsymbol{\kappa}_{i,n_q} \end{pmatrix}, \quad (38.8)$$

with the vectors $\mathbf{d}_{i,j}, \boldsymbol{\kappa}_{i,j} \in \mathbb{R}^3$ defined as

$$\mathbf{d}_{i,j} = \begin{cases} \mathbf{0}_{3 \times 1} & \text{if contact force } i \text{ does not affect joint } j, \\ \hat{\mathbf{z}}_j & \text{if joint } j \text{ is prismatic,} \\ \mathbf{S}(\mathbf{c}_i - \boldsymbol{\xi}_j)^T \hat{\mathbf{z}}_j & \text{if joint } j \text{ is revolute,} \end{cases}$$

$$\boldsymbol{\kappa}_{i,j} = \begin{cases} \mathbf{0}_{3 \times 1} & \text{if contact force } i \text{ does not affect joint } j, \\ \mathbf{0}_{3 \times 1} & \text{if joint } j \text{ is prismatic,} \\ \hat{\mathbf{z}}_j & \text{if joint } j \text{ is revolute,} \end{cases}$$

where $\boldsymbol{\xi}_j$ is the origin of the coordinate frame associated with the j -th joint and $\hat{\mathbf{z}}_j$ is the unit vector in the direction of the z -axis in the same frame, as shown in Fig. 38.12. Both vectors are expressed in $\{\mathbf{N}\}$. These frames may be assigned by any convenient method, for example, the Denavit–Hartenberg method [38.12]. The $\hat{\mathbf{z}}_j$ -axis is the rotational axis for revolute joints and the direction of translation for prismatic joints.

The final step in referring the hand twists to the contact frames is change the frame of expression of $\mathbf{v}_{i,\text{hnd}}^N$ and $\boldsymbol{\omega}_{i,\text{hnd}}^N$ to $\{\mathbf{C}\}_i$

$$\mathbf{v}_{i,\text{hnd}} = \bar{\mathbf{R}}_i^T \begin{pmatrix} \mathbf{v}_{i,\text{hnd}}^N \\ \boldsymbol{\omega}_{i,\text{hnd}}^N \end{pmatrix}. \quad (38.9)$$

Combining (38.9) and (38.7) yields the partial hand Jacobian $\tilde{\mathbf{J}}_i \in \mathbb{R}^{6 \times n_q}$, which relates the joint velocities to the contact twists on the hand

$$\mathbf{v}_{i,\text{hnd}} = \tilde{\mathbf{J}}_i \dot{\mathbf{q}}, \quad (38.10)$$

where

$$\tilde{\mathbf{J}}_i = \bar{\mathbf{R}}_i^T \mathbf{Z}_i. \quad (38.11)$$

To simplify notation, stack all the twists on the hand and object into the vectors $\mathbf{v}_{c,\text{hnd}} \in \mathbb{R}^{6n_c}$ and $\mathbf{v}_{c,\text{obj}} \in \mathbb{R}^{6n_c}$ as follows

$$\mathbf{v}_{c,\xi} = \begin{pmatrix} \mathbf{v}_{1,\xi}^T & \cdots & \mathbf{v}_{n_c,\xi}^T \end{pmatrix}^T, \quad \xi = \{\text{obj}, \text{hnd}\}.$$

Now the *complete grasp matrix* $\tilde{\mathbf{G}} \in \mathbb{R}^{6 \times 6n_c}$ and *complete hand Jacobian* $\tilde{\mathbf{J}} \in \mathbb{R}^{6n_c \times n_q}$ relate the various velocity quantities as follows

$$\mathbf{v}_{c,\text{obj}} = \tilde{\mathbf{G}}^T \mathbf{v}, \quad (38.12)$$

$$\mathbf{v}_{c,\text{hnd}} = \tilde{\mathbf{J}} \dot{\mathbf{q}}, \quad (38.13)$$

where

$$\tilde{\mathbf{G}}^T = \begin{pmatrix} \tilde{\mathbf{G}}_1^T \\ \vdots \\ \tilde{\mathbf{G}}_{n_c}^T \end{pmatrix}, \quad \tilde{\mathbf{J}} = \begin{pmatrix} \tilde{\mathbf{J}}_1 \\ \vdots \\ \tilde{\mathbf{J}}_{n_c} \end{pmatrix}. \quad (38.14)$$

The term *complete* is used to emphasize that all $6n_c$ twist components at the contacts are included in the mapping. See Example 1, Part 1 and Example 3, Part 1 at the end of this chapter for clarification.

Contact Modeling

Contacts play a central role in grasping. Contacts allow to impose a given motion to the object or to apply a given force through the object. All grasping actions go through contacts whose model and control is crucial in grasping. Three contact models useful for grasp analysis are reviewed here. For a complete discussion of contact modeling in robotics, readers are referred to Chap. 37.

The three models of greatest interest in grasp analysis are known as *point-contact-without-friction*, *hard-finger*, and *soft-finger* [38.13]. These models select components of the contact twists to transmit between the hand and the object. This is done by equating a subset of the components of the hand and object twist at each contact. The corresponding components of the contact force and moment are also equated, but without regard for the constraints imposed by a friction model (Sect. 38.4.2).

The point-contact-without-friction (**PwoF**) model is used when the contact patch is very small and the surfaces of the hand and object are slippery. With this model, only the normal component of the translational velocity of the contact point on the hand (i.e., the first component of $\mathbf{v}_{i,\text{hnd}}$) is transmitted to the object. The two components of tangential velocity and the three components of angular velocity are not transmitted. Analogously, the normal component of the contact force is transmitted, but the frictional forces and moments are assumed to be negligible.

A hard finger (**HF**) model is used when there is significant contact friction, but the contact patch is small, so that no appreciable friction moment exists. When this model is applied to a contact, all three translational velocity components of the contact point on the hand (i.e., the first three components of $\mathbf{v}_{i,\text{hnd}}$) and all three components of the contact force are transmitted through the contact. None of the angular velocity components or moment components are transmitted.

The soft finger (**SF**) model is used in situations in which the surface friction and the contact patch are large enough to generate significant friction forces and a friction moment about the contact normal. At a contact where this model is enforced, the three translational velocity components of the contact on the hand and the angular velocity component about the contact normal are transmitted (i.e., the first four components of $\mathbf{v}_{i,\text{hnd}}$). Similarly, all three components of contact force

and the normal component of the contact moment are transmitted.

Remark 38.1

The reader may see a contradiction between the rigid-body assumption and the soft-finger model. The rigid-body assumption is an approximation that simplifies all aspects of the analysis of grasping, but nonetheless is sufficiently accurate in many real situations. Without it, grasp analysis would be impractical. On the other hand, the need for a soft-finger model is a clear admission that the finger links and object are not rigid. However, it can be usefully applied in situations in which the amount of deformation required to obtain a large contact patch is small. Such situations occur when the local surface geometries are similar. If large finger or body deformations exist in the real system, the rigid-body approach presented in this chapter should be used with caution.

To develop the **PwoF**, **HF**, and **SF** models, define the relative twist at contact i as follows

$$\begin{pmatrix} \tilde{\mathbf{J}}_i & -\tilde{\mathbf{G}}_i^T \end{pmatrix} \begin{pmatrix} \dot{\mathbf{q}} \\ \mathbf{v} \end{pmatrix} = \mathbf{v}_{i,\text{hnd}} - \mathbf{v}_{i,\text{obj}}.$$

A particular contact model is defined through the matrix $\mathbf{H}_i \in \mathbb{R}^{n_{\lambda i} \times 6}$, which selects $n_{\lambda i}$ components of the relative contact twist and sets them to zero

$$\mathbf{H}_i(\mathbf{v}_{i,\text{hnd}} - \mathbf{v}_{i,\text{obj}}) = \mathbf{0}.$$

These components are referred to as transmitted degrees of freedom (**DOF**). Define \mathbf{H}_i as follows

$$\mathbf{H}_i = \left[\begin{array}{c|c} \mathbf{H}_{iF} & \mathbf{0} \\ \hline \mathbf{0} & \mathbf{H}_{iM} \end{array} \right], \quad (38.15)$$

where \mathbf{H}_{iF} and \mathbf{H}_{iM} are the translational and rotational component selection matrices. Table 38.2 gives the definitions of the selection matrices for the three contact models, where *vacuous* for \mathbf{H}_{iM} means that the corresponding block row matrix in (38.15) is void (i.e., it has zero rows and columns). Notice that for the **SF** model, \mathbf{H}_{iM} selects rotation about the contact normal.

After choosing a transmission model for each contact, the kinematic contact constraint equations for all n_c contacts can be written in compact form as

$$\mathbf{H}(\mathbf{v}_{c,\text{hnd}} - \mathbf{v}_{c,\text{obj}}) = \mathbf{0}, \quad (38.16)$$

Table 38.2 Selection matrices for three contact models

Model	$n_{\lambda i}$	\mathbf{H}_{iF}	\mathbf{H}_{iM}
PwoF	1	(1 0 0)	Vacuous
HF	3	$\mathbf{I}_{3 \times 3}$	Vacuous
SF	4	$\mathbf{I}_{3 \times 3}$	(1 0 0)

where

$$\mathbf{H} = \text{Blockdiag}(\mathbf{H}_1, \dots, \mathbf{H}_{n_c}) \in \mathbb{R}^{n_\lambda \times 6n_c},$$

and the number of twist components n_λ transmitted through the n_c contacts is given by $n_\lambda = \sum_{i=1}^{n_c} n_{\lambda i}$.

Finally, by substituting (38.12) and (38.13) into (38.16) one gets the compact form of the velocity kinematic contact constraints

$$(\mathbf{J} \quad -\mathbf{G}^T) \begin{pmatrix} \dot{\mathbf{q}} \\ \mathbf{v} \end{pmatrix} = \mathbf{0}, \quad (38.17)$$

where the grasp matrix and hand Jacobian are finally defined as

$$\begin{aligned} \mathbf{G}^T &= \mathbf{H}\tilde{\mathbf{G}}^T \in \mathbb{R}^{n_\lambda \times 6}, \\ \mathbf{J} &= \mathbf{H}\tilde{\mathbf{J}} \in \mathbb{R}^{n_\lambda \times n_q}. \end{aligned} \quad (38.18)$$

For more details on the construction of \mathbf{H} , the grasp matrix, and the hand Jacobian, readers are referred to [38.14–16] and the references therein. Also, see Example 1, Part 2 and Example 3, Part 2.

It is worth noting that (38.17) can be written in the following form

$$\mathbf{J}\dot{\mathbf{q}} = \mathbf{v}_{\text{cc,hnd}} = \mathbf{v}_{\text{cc,obj}} = \mathbf{G}^T \mathbf{v}, \quad (38.19)$$

where $\mathbf{v}_{\text{cc,hnd}}$ and $\mathbf{v}_{\text{cc,obj}}$ contain only the components of the twists that are transmitted by the contacts. To underline the central role of contact constraints in grasping, it is worth noting that *grasp maintenance* is defined as the situation in which constraints (38.19) are maintained over time. The kinematic contact constraint holds only if the contact force satisfies the friction constraints for the contact models with friction or the unilateral constraint for the contact model without friction (Sect. 38.4.2).

Thus, when a contact is frictionless, contact maintenance implies continued contact, but sliding is allowed. However, when a contact is of the type HF, contact maintenance implies sticking contact, since sliding would violate the HF model. Similarly, for a SF contact, there may be no sliding or relative rotation about the contact normal.

For the remainder of this chapter, it will be assumed that $\mathbf{v}_{\text{cc,hnd}} = \mathbf{v}_{\text{cc,obj}}$, so the notation will be shortened to \mathbf{v}_{cc} .

Planar Simplifications

Assume that the plane of motion is the (x, y) -plane of $\{N\}$. The vectors \mathbf{v} and \mathbf{g} reduce in dimension

from six to three by dropping components three, four, and five. The dimensions of vectors \mathbf{c}_i and \mathbf{p} reduce from three to two. The i -th rotation matrix becomes $\mathbf{R}_i = [\hat{\mathbf{n}}_i \hat{\mathbf{t}}_i] \in \mathbb{R}^{2 \times 2}$ (where the third component of $\hat{\mathbf{n}}_i$ and $\hat{\mathbf{t}}_i$ is dropped) and (38.4) holds with $\tilde{\mathbf{R}}_i = \text{Blockdiag}(\mathbf{R}_i, 1) \in \mathbb{R}^{3 \times 3}$. Equation (38.2) holds with

$$\mathbf{P}_i = \begin{pmatrix} \mathbf{I}_{2 \times 2} & \mathbf{0} \\ \mathbf{S}_2(\mathbf{c}_i - \mathbf{p}) & 1 \end{pmatrix},$$

where \mathbf{S}_2 is the analog of the cross product matrix for two-dimensional vectors, given as

$$\mathbf{S}_2(\mathbf{r}) = \begin{pmatrix} -r_y & r_x \end{pmatrix}.$$

Equation (38.7) holds with $\mathbf{d}_{i,j} \in \mathbb{R}^2$ and $\kappa_{i,j} \in \mathbb{R}$ defined as

$$\mathbf{d}_{i,j} = \begin{cases} \mathbf{0}_{2 \times 1} & \text{if contact force } i \text{ does not affect the joint } j, \\ \hat{\mathbf{z}}_j & \text{if joint } j \text{ is prismatic,} \\ \mathbf{S}(\mathbf{c}_i - \boldsymbol{\xi}_j)^T & \text{if joint } j \text{ is revolute,} \end{cases}$$

$$\kappa_{i,j} = \begin{cases} 0 & \text{if contact force } i \text{ does not affect joint } j, \\ 0 & \text{if joint } j \text{ is prismatic,} \\ 1 & \text{if joint } j \text{ is revolute.} \end{cases}$$

The complete grasp matrix and hand Jacobian have reduced sizes: $\tilde{\mathbf{G}}^T \in \mathbb{R}^{3n_c \times 3}$ and $\tilde{\mathbf{J}} \in \mathbb{R}^{3n_c \times n_q}$. As far as contact constraint is concerned, (38.15) holds with \mathbf{H}_{IF} and \mathbf{H}_{IM} defined in Table 38.3.

In the planar case, the SF and HF models are equivalent, because the object and the hand lie in a plane. Rotations about the contact normals would cause out-of-plane motions. Finally, the dimensions of the grasp matrix and hand Jacobian are reduced to the following sizes: $\mathbf{G}^T \in \mathbb{R}^{n_\lambda \times 3}$ and $\mathbf{J} \in \mathbb{R}^{n_\lambda \times n_q}$. See Example 1, Part 3 and Example 2, Part 1.

38.1.2 Dynamics and Equilibrium

Dynamic equations of the system can be written as

$$\begin{aligned} \mathbf{M}_{\text{hnd}}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{b}_{\text{hnd}}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{J}^T \boldsymbol{\lambda} &= \boldsymbol{\tau}_{\text{app}} \\ \mathbf{M}_{\text{obj}}(\mathbf{u})\ddot{\mathbf{v}} + \mathbf{b}_{\text{obj}}(\mathbf{u}, \mathbf{v}) - \mathbf{G}\boldsymbol{\lambda} &= \mathbf{g}_{\text{app}} \end{aligned} \quad (38.20)$$

subject to constraint (38.17),

Table 38.3 Definitions

Model	$n_{\lambda i}$	\mathbf{H}_{IF}	\mathbf{H}_{IM}
PwoF	1	$\begin{pmatrix} 1 & 0 \end{pmatrix}$	Vacuous
HF/SF	2	$\mathbf{I}_{2 \times 2}$	Vacuous

Table 38.4 Vectors of contact force and moment components, also known as the wrench intensity vector, transmitted through contact i

Model	λ_i
PwoF	(f_{in})
HF	$(f_{in} f_{it} f_{io})^T$
SF	$(f_{in} f_{it} f_{io} m_{in})^T$

where $\mathbf{M}_{\text{hnd}}(\cdot)$ and $\mathbf{M}_{\text{obj}}(\cdot)$ are symmetric, positive definite inertia matrices, $\mathbf{b}_{\text{hnd}}(\cdot, \cdot)$ and $\mathbf{b}_{\text{obj}}(\cdot, \cdot)$ are the velocity-product terms, \mathbf{g}_{app} is the force and moment applied to the object by gravity and other external sources, $\boldsymbol{\tau}_{\text{app}}$ is the vector of external loads and actuator actions, and the vector $\mathbf{G}\boldsymbol{\lambda}$ is the total wrench applied to the object by the hand. The vector $\boldsymbol{\lambda}$ contains the contact force and moment components transmitted through the contacts and expressed in the contact frames. Specifically, $\boldsymbol{\lambda} = [\lambda_1^T \cdots \lambda_n^T]^T$, where

$$\lambda_i = \mathbf{H}_i [f_{in} f_{it} f_{io} m_{in} m_{it} m_{io}]^T.$$

The subscripts indicate one normal (n) and two tangential (t,o) components of contact force \mathbf{f} and moment \mathbf{m} . For a SF, HF, or PwoF contact, λ_i is defined as in Table 38.4. Finally, it is worth noting that $\mathbf{G}_i \lambda_i = \tilde{\mathbf{G}}_i \mathbf{H}_i^T \lambda_i$ is the wrench applied through contact i , where $\tilde{\mathbf{G}}_i$ and \mathbf{H}_i are defined in (38.6) and (38.15). The vector λ_i is known as the wrench intensity vector for contact i .

Equation (38.20) represents the dynamics of the hand and object without regard for the kinematic constraints imposed by the contact models. Enforcing them, the dynamic model of the system can be written as follows

$$\begin{pmatrix} \mathbf{J}^T \\ -\mathbf{G} \end{pmatrix} \boldsymbol{\lambda} = \begin{pmatrix} \boldsymbol{\tau} \\ \mathbf{g} \end{pmatrix} \quad (38.21)$$

subject to $\mathbf{J}\dot{\mathbf{q}} = \mathbf{G}^T \mathbf{v} = \mathbf{v}_{\text{cc}}$, where

$$\begin{aligned} \boldsymbol{\tau} &= \boldsymbol{\tau}_{\text{app}} - \mathbf{M}_{\text{hnd}}(\mathbf{q})\ddot{\mathbf{q}} - \mathbf{b}_{\text{hnd}}(\mathbf{q}, \dot{\mathbf{q}}) \\ \mathbf{g} &= \mathbf{g}_{\text{app}} - \mathbf{M}_{\text{obj}}(\mathbf{u})\ddot{\mathbf{v}} - \mathbf{b}_{\text{obj}}(\mathbf{u}, \mathbf{v}). \end{aligned} \quad (38.22)$$

One should notice that the dynamic equations are closely related to the velocity kinematic model in (38.17). Specifically, just as \mathbf{J} and \mathbf{G}^T transmit only selected components of contact twists, \mathbf{J}^T and \mathbf{G} in (38.20) serve to transmit only the corresponding components of the contact wrenches.

When the inertia terms are negligible, as occurs during slow motion, the system is said to be quasi-static. In this case, (38.22) becomes

$$\begin{aligned} \boldsymbol{\tau} &= \boldsymbol{\tau}_{\text{app}}, \\ \mathbf{g} &= \mathbf{g}_{\text{app}}, \end{aligned} \quad (38.23)$$

and does not depend on joint and object velocities. Consequently, when the grasp is in static equilibrium or moves quasi-statically, one can solve the first equation and the constraint in (38.21) independently to compute $\boldsymbol{\lambda}$, $\dot{\mathbf{q}}$, and \mathbf{v} . It is worth noting that such a force/velocity decoupled solution is not possible when dynamic effects are appreciable, since the first equation in (38.21) depends on the third one through (38.22).

Remark 38.2

Equation (38.21) highlights an important alternative view of the grasp matrix and the hand Jacobian. \mathbf{G} can be thought of as a mapping from the transmitted contact forces and moments to the set of wrenches that the hand can apply to the object, while \mathbf{J}^T can be thought of as a mapping from the transmitted contact forces and moments to the vector of joint loads. Notice that these interpretations hold for both dynamic and quasi-static conditions.

38.2 Controllable Twists and Wrenches

In hand design and in grasp and manipulation planning, it is important to know the set of twists that can be imparted to the object by movements of the fingers, and conversely, the conditions under which the hand can prevent all possible motions of the object. The dual view is that one needs to know the set of wrenches that the hand can apply to the object and under what conditions any wrench in \mathbb{R}^6 can be applied through the contacts. This knowledge will be gained by studying the various subspaces associated with \mathbf{G} and \mathbf{J} [38.17].

The spaces, shown in Fig. 38.3, are the column spaces and null spaces of \mathbf{G} , \mathbf{G}^T , \mathbf{J} , and \mathbf{J}^T . Column

space (also known as range) and null space will be denoted by $\mathcal{R}(\cdot)$ and $\mathcal{N}(\cdot)$, respectively. The arrows show the propagation of the various velocity and load quantities through the grasping system. For example, in the left part of Fig. 38.3 it is shown how any vector $\dot{\mathbf{q}} \in \mathbb{R}^{n_q}$ can be decomposed into a sum of two orthogonal vectors in $\mathcal{R}(\mathbf{J}^T)$ and in $\mathcal{N}(\mathbf{J})$ and how $\dot{\mathbf{q}}$ is mapped to $\mathcal{R}(\mathbf{J})$ by multiplication by \mathbf{J} .

It is important to recall two facts from linear algebra. First, a matrix \mathbf{A} maps vectors from $\mathcal{R}(\mathbf{A}^T)$ to $\mathcal{R}(\mathbf{A})$ in a one-to-one and onto fashion, that is, the map \mathbf{A} is a bijection. The generalized inverse \mathbf{A}^+ of

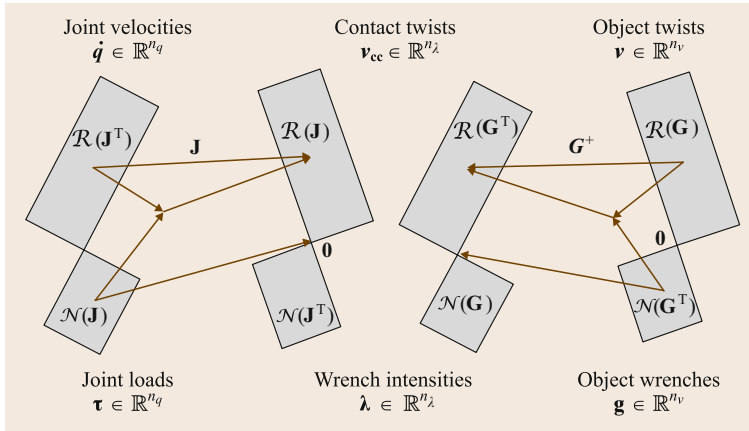

Fig. 38.3 Linear maps relating twists and wrenches of a grasping system

\mathbf{A} is a bijection that maps vectors in the opposite direction [38.18]. Also, \mathbf{A} maps all vectors in $\mathcal{N}(\mathbf{A})$ to zero. Finally, there is no non-trivial vector that \mathbf{A} can map into $\mathcal{N}(\mathbf{A}^T)$. This implies that if $\mathcal{N}(\mathbf{G}^T)$ is non-trivial, then the hand will not be able to control all degrees of freedom of the object's motion. This is certainly true for quasi-static grasping, but when dynamics are important, they may cause the object to move along the directions in $\mathcal{N}(\mathbf{G}^T)$.

38.2.1 Grasp Classifications

The four null spaces motivate a basic classification of grasping systems defined in Table 38.5. Assuming solutions to (38.21) exist, the following force and velocity equations provide insight into the physical meaning of the various null spaces

$$\dot{\mathbf{q}} = \mathbf{J}^+ \mathbf{v}_{cc} + \mathbf{N}(\mathbf{J}) \boldsymbol{\gamma}, \quad (38.24)$$

$$\mathbf{v} = (\mathbf{G}^T)^+ \mathbf{v}_{cc} + \mathbf{N}(\mathbf{G}^T) \boldsymbol{\gamma}, \quad (38.25)$$

$$\boldsymbol{\lambda} = -\mathbf{G}^+ \mathbf{g} + \mathbf{N}(\mathbf{G}) \boldsymbol{\gamma}, \quad (38.26)$$

$$\boldsymbol{\lambda} = (\mathbf{J}^T)^+ \boldsymbol{\tau} + \mathbf{N}(\mathbf{J}^T) \boldsymbol{\gamma}. \quad (38.27)$$

In these equations, \mathbf{A}^+ denotes the generalized inverse, henceforth pseudoinverse, of a matrix \mathbf{A} , $\mathbf{N}(\mathbf{A})$ denotes

a matrix whose columns form a basis for $\mathcal{N}(\mathbf{A})$, and $\boldsymbol{\gamma}$ is an arbitrary vector of appropriate dimension that parameterizes the solution sets. If not otherwise specified, the context will make clear if the generalized inverse is left or right.

If the null spaces represented in the equations are non-trivial, then one immediately sees the first many-to-one mapping in Table 38.5. To see the other many-to-one mappings, and in particular the defective class, consider (38.24). It can be rewritten with \mathbf{v}_{cc} decomposed into orthogonal components \mathbf{v}_{rs} and \mathbf{v}_{lns} in $\mathcal{R}(\mathbf{J})$ and $\mathcal{N}(\mathbf{J}^T)$, respectively

$$\dot{\mathbf{q}} = \mathbf{J}^+ (\mathbf{v}_{rs} + \mathbf{v}_{lns}) + \mathbf{N}(\mathbf{J}) \boldsymbol{\gamma}. \quad (38.28)$$

Recall that every vector in $\mathcal{N}(\mathbf{A}^T)$ is orthogonal to every row of \mathbf{A}^+ . Therefore $\mathbf{J}^+ \mathbf{v}_{lns} = \mathbf{0}$. If $\boldsymbol{\gamma}$ and \mathbf{v}_{rs} are fixed in (38.28), then $\dot{\mathbf{q}}$ is unique. Thus it is clear that if $\mathcal{N}(\mathbf{J}^T)$ is non-trivial, then a subspace of twists of the hand at the contacts will map to a single joint velocity vector. Applying the same approach to the other three equations (38.25)–(38.27) yields the other many-to-one mappings listed in Table 38.5.

Equations (38.21) and (38.24)–(38.27), motivate the following definitions.

Definition 38.1 Redundant

A grasping system is said to be *redundant* if $\mathcal{N}(\mathbf{J})$ is non-trivial.

Joint velocities $\dot{\mathbf{q}}$ in $\mathcal{N}(\mathbf{J})$ are referred to as *internal hand velocities*, since they correspond to finger motions, but do not generate motion of the hand in the constrained directions at the contact points. If the quasi-static model applies, it can be shown that these motions are not influenced by the motion of the object and vice versa.

Table 38.5 Basic grasp classes

Condition	Class	Many-to-one
$\mathcal{N}(\mathbf{J}) \neq \mathbf{0}$	Redundant	$\dot{\mathbf{q}} \rightarrow \mathbf{v}_{cc}$ $\boldsymbol{\tau} \rightarrow \boldsymbol{\lambda}$
$\mathcal{N}(\mathbf{G}^T) \neq \mathbf{0}$	Indeterminate	$\mathbf{v} \rightarrow \mathbf{v}_{cc}$ $\mathbf{g} \rightarrow \boldsymbol{\lambda}$
$\mathcal{N}(\mathbf{G}) \neq \mathbf{0}$	Graspable	$\boldsymbol{\lambda} \rightarrow \mathbf{g}$ $\mathbf{v}_{cc} \rightarrow \mathbf{v}$
$\mathcal{N}(\mathbf{J}^T) \neq \mathbf{0}$	Defective	$\boldsymbol{\lambda} \rightarrow \boldsymbol{\tau}$ $\mathbf{v}_{cc} \rightarrow \dot{\mathbf{q}}$

Definition 38.2 Indeterminate

A grasping system is said to be *indeterminate* if $\mathcal{N}(\mathbf{G}^T)$ is non-trivial.

Object twists \mathbf{v} in $\mathcal{N}(\mathbf{G}^T)$ are called *internal object twists*, since they correspond to motions of the object, but do not cause motion of the object in the constrained directions at the contacts. If the static model applies, it can be shown that these twists cannot be controlled by finger motions.

Definition 38.3 Graspable

A grasping system is said to be *graspable* if $\mathcal{N}(\mathbf{G})$ is non-trivial.

Wrench intensities $\boldsymbol{\lambda}$ in $\mathcal{N}(\mathbf{G})$ are referred to as *internal object forces*. These wrenches are *internal* because they do not contribute to the acceleration of the object, i. e., $\mathbf{G}\boldsymbol{\lambda} = \mathbf{0}$. Instead, these wrench intensities affect the tightness of the grasp. Thus, internal wrench intensities play a fundamental role in maintaining grasps that rely on friction (Sect. 38.4.2).

Definition 38.4 Defective

A grasping system is said to be *defective* if $\mathcal{N}(\mathbf{J}^T)$ is non-trivial.

Wrench intensities $\boldsymbol{\lambda}$ in $\mathcal{N}(\mathbf{J}^T)$ are called *internal hand forces*. These forces do not influence the hand joint dynamics given in (38.20). If the static model is considered, it can be easily shown that wrench intensities belonging to $\mathcal{N}(\mathbf{J}^T)$ cannot be generated by joint actions, but can be resisted by the structure of the hand.

See Example 1, Part 4, Example 2, Part 2 and Example 3, Part 3.

38.2.2 Limitations of Rigid-Body Formulation

The rigid-body dynamics equation (38.20) can be rewritten with Lagrange multipliers associated with the contact constraints as

$$\mathbf{M}_{\text{dyn}} \begin{pmatrix} \ddot{\mathbf{q}} \\ \dot{\mathbf{v}} \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} \boldsymbol{\tau} - \mathbf{b}_{\text{hnd}} \\ \mathbf{v} - \mathbf{b}_{\text{obj}} \\ \mathbf{b}_c \end{pmatrix}, \quad (38.29)$$

where $\mathbf{b}_c = [\partial(\mathbf{J}\dot{\mathbf{q}})/\partial\mathbf{q}]\dot{\mathbf{q}} - [\partial(\mathbf{G}\mathbf{v})/\partial\mathbf{u}]\dot{\mathbf{u}}$ and

$$\mathbf{M}_{\text{dyn}} = \begin{pmatrix} \mathbf{M}_{\text{hnd}} & \mathbf{0} & \mathbf{J}^T \\ \mathbf{0} & \mathbf{M}_{\text{obj}} & -\mathbf{G} \\ \mathbf{J} & -\mathbf{G}^T & \mathbf{0} \end{pmatrix}.$$

In order for this equation to completely determine the motion of the system, it is necessary that matrix \mathbf{M}_{dyn} be invertible. This case is considered in detail in [38.19], where the dynamics of multi-finger manipulation is studied under the hypothesis that the hand Jacobian is full row rank, i. e., $\mathcal{N}(\mathbf{J}^T) = \mathbf{0}$. For all manipulation systems with non-invertible \mathbf{M}_{dyn} , rigid-body dynamics fails to determine the motion and the wrench intensity vector. By observing that

$$\begin{aligned} \mathcal{N}(\mathbf{M}_{\text{dyn}}) \\ = \{(\ddot{\mathbf{q}}, \dot{\mathbf{v}}, \boldsymbol{\lambda})^T | \ddot{\mathbf{q}} = \mathbf{0}, \dot{\mathbf{v}} = \mathbf{0}, \boldsymbol{\lambda} \in \mathcal{N}(\mathbf{J}^T) \cap \mathcal{N}(\mathbf{G})\}, \end{aligned}$$

the same arguments apply under quasi-static conditions defined by (38.21) and (38.23). When $\mathcal{N}(\mathbf{J}^T) \cap \mathcal{N}(\mathbf{G}) \neq \mathbf{0}$, the rigid-body approach fails to solve the first equation in (38.21), thus leaving $\boldsymbol{\lambda}$ indeterminate.

Definition 38.5 Hyperstatic

A grasping system is said to be *hyperstatic* if

$$\mathcal{N}(\mathbf{J}^T) \cap \mathcal{N}(\mathbf{G})$$

is non-trivial.

In such systems there are internal forces (Definition 38.3) belonging to $\mathcal{N}(\mathbf{J}^T)$ that are not controllable as discussed for defective grasps. Rigid-body dynamics is not satisfactory for hyperstatic grasps, since the rigid-body assumption leads to undetermined contact wrenches [38.20].

See Example 3, Part 3.

38.2.3 Desirable Properties

For a general purpose grasping system, there are three main desirable properties: control of the object twist \mathbf{v} , control of object wrench \mathbf{g} , and control of the internal forces. Control of these quantities implies that the hand can deliver the desired \mathbf{v} and \mathbf{g} with specified grip pressure by the appropriate choice of joint velocities and actions. The conditions on \mathbf{J} and \mathbf{G} equivalent to these properties are given in Table 38.6.

We derive the conditions in two steps. First, we ignore the structure and configuration of the hand (captured in \mathbf{J}) by assuming that each contact point on each

Table 38.6 Desirable properties of a grasp

Task requirement	Required conditions
All wrenches possible, \mathbf{g} } All twists possible, \mathbf{v} }	$\text{rank}(\mathbf{G}) = n_v$
Control all wrenches, \mathbf{g} } Control all twists, \mathbf{v} }	$\text{rank}(\mathbf{GJ}) = \text{rank}(\mathbf{G}) = n_v$
Control all internal forces	$\mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^T) = \mathbf{0}$

Fig. 38.4 The Salisbury Hand

finger can be commanded to move in any direction transmitted by the chosen contact model. An important perspective here is that \mathbf{v}_{cc} is seen as the independent input variable and \mathbf{v} is seen as the output. The dual interpretation is that the actuators can generate any contact force and moment in the constrained directions at each contact. Similarly, λ is seen as the input and \mathbf{g} is seen as the output. The primary property of interest under this assumption is whether or not the arrangement and types of contacts on the object (captured in \mathbf{G}) are such that a sufficiently dexterous hand could control its fingers so as to impart any twist $\mathbf{v} \in \mathbb{R}^6$ to the object and, similarly, to apply any wrench $\mathbf{g} \in \mathbb{R}^6$ to the object.

All Object Twists Possible

Given a set of contact locations and types, by solving (38.19) for \mathbf{v} or observing the map \mathbf{G} on the right side of Fig. 38.3, one sees that the achievable object twists are those in $\mathcal{R}(\mathbf{G})$. Those in $\mathcal{N}(\mathbf{G}^T)$ cannot be achieved by any hand using the given grasp. Therefore, to achieve any object twist, we must have: $\mathcal{N}(\mathbf{G}^T) = \mathbf{0}$, or equivalently, $\text{rank}(\mathbf{G}) = n_v$. Any grasp with three non-collinear hard contacts or two distinct soft contacts satisfies this condition.

All Object Wrenches Possible

This case is the dual of the previous case, so we expect the same condition. From (38.21), one immediately obtains the condition $\mathcal{N}(\mathbf{G}^T) = \mathbf{0}$, so again we have $\text{rank}(\mathbf{G}) = n_v$.

To obtain the conditions needed to control the various quantities of interest, the structure of the hand

cannot be ignored. Recall that the only achievable contact twists on the hand are in $\mathcal{R}(\mathbf{J})$, which is not necessarily equal to \mathbb{R}^{n_λ} .

Control All Object Twists

By solving (38.17) for \mathbf{v} , one sees that in order to cause any object twist \mathbf{v} by choice of joint velocities $\dot{\mathbf{q}}$, we must have $\mathcal{R}(\mathbf{G}\mathbf{J}) = \mathbb{R}^{n_v}$ and $\mathcal{N}(\mathbf{G}^T) = \mathbf{0}$. These conditions are equivalent to $\text{rank}(\mathbf{G}\mathbf{J}) = \text{rank}(\mathbf{G}) = n_v$.

Control All Object Wrenches

This property is dual to the previous one. Analysis of (38.21) yields the same conditions:

$$\text{rank}(\mathbf{G}\mathbf{J}) = \text{rank}(\mathbf{G}) = n_v.$$

Control All Internal Forces

Equation (38.20) shows that wrench intensities with no effect on object motion are those in $\mathcal{N}(\mathbf{G})$. In general, not all the internal forces may be actively controlled by joint actions. In [38.16, 21] it has been shown that all internal forces in $\mathcal{N}(\mathbf{G})$ are controllable if and only if $\mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^T) = \mathbf{0}$.

See Example 1, Part 5 and Example 2, Part 3.

Design Considerations of the Salisbury Hand

The Salisbury Hand in Fig. 38.4 was designed to have the smallest number of joints that would meet all the task requirements in Table 38.6. Assuming HF contacts, three non-collinear contacts is the minimum number such that $\text{rank}(\mathbf{G}) = n_v = 6$. In this case, \mathbf{G} has six rows and nine columns and the dimension of $\mathcal{N}(\mathbf{G})$ is three [38.2, 8]. The ability to control all internal forces and apply an arbitrary wrench to the object requires that $\mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^T) = \mathbf{0}$, so the minimum dimension of the column space of \mathbf{J} is nine. To achieve this, the hand must have at least nine joints, which Salisbury implemented as three fingers, each with three revolute joints.

The intended way to execute a dexterous manipulation task with the Salisbury Hand is to grasp the object at three non-collinear points with the fingertips, forming a grasp triangle. To secure the grasp, the internal forces are controlled so that the contact points are maintained without sliding. Dexterous manipulation can be thought of as moving the fingertips to control the positions of the vertices of the grasp triangle.

38.3 Compliant Grasps

In this section we extend the rigid-body model to include compliance. This is needed to design controllers that can implement desired compliance behaviors of a grasped object when it contacts the environment, which can increase the robustness of static grasps and dexterous manipulation tasks. It also facilitates the analysis of hands designed with flexible mechanical elements [38.22, 23] and grasp control strategies that exploit grasp *synergies* [38.24, 25]. Thanks to compliance, hands can be designed to maintain a secure grasp with fewer joints, which provides greater mechanical robustness and reduces the complexity of planning grasps.

On the other hand, reducing the number of DOFs in robotic hands demands a compliant design of the whole structure to adapt the shape of the hand to different objects and to improve robustness with respect to uncertainties [38.26]. Compliance can be passive or active. Passive compliance is due to the structural deformation of robot components, including joints, while active compliance refers to virtual elasticity of actuators, e.g., due to the proportional action of a PD joint controller, that can be actively set by changing the control parameters [38.26–29].

In the following, we extend the grasp analysis relaxing the rigid-body contact constraints to take into account both the compliance and the low number of DOFs in robotic hands.

If the hand structure is not perfectly stiff, as shown in Fig. 38.5, the actual vector of joint variables \mathbf{q} can be different from the reference one \mathbf{q}_r , given to the joint actuator controllers, and their difference is related to the joint effort $\boldsymbol{\tau}$ through a compliance matrix $\mathbf{C}_q \in \mathbb{R}^{n_q \times n_q}$ by the constitutive equation

$$\mathbf{q}_r - \mathbf{q} = \mathbf{C}_q \boldsymbol{\tau} . \quad (38.30)$$

Note that if the hand structure is perfectly rigid, $\mathbf{C}_q = 0$ and the hand stiffness $\mathbf{K}_q = \mathbf{C}_q^{-1}$ is not defined.

It will be clear in a moment that to deal with a low number of DOFs of the hand, a compliant model of the contact must be considered. According to Definition 38.4, in case of a low number of DOFs, it is very likely that the grasp will be defective, i.e., with a non-trivial $\mathcal{N}(\mathbf{J}^T)$. It is worth noting that this typically happens also in power grasps [38.30] where the hand envelops the object establishing contacts even with inner limbs. In this case the hand Jacobian is a tall matrix with a non-trivial null space of its transpose.

If the system is very defective, it is very likely that the grasp will be hyperstatic according to Def-

Fig. 38.5 Compliant joints and compliant contacts, main definitions

inition 38.5 and consequently the rigid-body model in (38.21) is under-determined and does not admit a unique solution for the contact force vector $\boldsymbol{\lambda}$ as discussed in Sect. 38.2.2. Note that computing the force distribution $\boldsymbol{\lambda}$ is crucial in grasp analysis since it allows one to evaluate if the contact constraints are fulfilled, and consequently, if the grasp will be maintained.

The force distribution problem in hyperstatic grasps is an under-determined problem of statics under the assumption of rigid contacts of (38.17). To solve the problem, we need to enrich the model with more information on the contact forces. A possible solution is to substitute the rigid-body kinematic constraint (38.19) with a compliant model of the contact interaction [38.21], obtained introducing a set of springs between the contact points on the hand \mathbf{c}^h and on the object \mathbf{c}^o as shown in Fig. 38.5

$$\mathbf{C}_c \boldsymbol{\lambda} = \mathbf{c}^h - \mathbf{c}^o , \quad (38.31)$$

where $\mathbf{C}_c \in \mathbb{R}^{n_\lambda \times n_\lambda}$ is the contact compliance matrix which is symmetric and positive definite. The contact stiffness matrix is defined as the reciprocal of the contact compliance matrix $\mathbf{K}_c = \mathbf{C}_c^{-1}$.

The analysis is presented in a quasi-static framework: from an equilibrium reference configuration $\mathbf{q}_{r,0}$, \mathbf{q}_0 , $\boldsymbol{\tau}_0$, $\boldsymbol{\lambda}_0$, \mathbf{u}_0 and \mathbf{g}_0 , a small input perturbation is applied to the joint references $\mathbf{q}_{r,0} + \Delta \mathbf{q}_r$ and to the external load $\mathbf{g}_0 + \Delta \mathbf{g}$ which moves the grasp system to a new equilibrium configuration whose linear approximation is represented by $\mathbf{q}_0 + \Delta \mathbf{q}$, $\boldsymbol{\tau}_0 + \Delta \boldsymbol{\tau}$, $\boldsymbol{\lambda}_0 + \Delta \boldsymbol{\lambda}$, $\mathbf{u}_0 + \Delta \mathbf{u}$.

In the following, for the sake of simplicity, it is convenient to refer \mathbf{G} and \mathbf{J} matrices to the object reference frame $\{\mathbf{B}\}$ and not to the inertial frame $\{\mathbf{N}\}$ as previously described. Note that this only applies to this section on compliance analysis, while the rest of this chapter still refers to matrices \mathbf{G} and \mathbf{J} as described in Sect. 38.1.1.

Let $\mathbf{R}_b \in \mathbb{R}^{3 \times 3}$ represent the orientation of the object frame $\{\mathbf{B}\}$ with respect to the inertial frame. Then the object twist referred to $\{\mathbf{B}\}$ is given as

$$\mathbf{v}_{i,\text{obj}} = \bar{\mathbf{R}}_b^T \begin{pmatrix} \mathbf{v}_{i,\text{obj}}^N \\ \boldsymbol{\omega}_{i,\text{obj}}^N \end{pmatrix}, \quad (38.32)$$

where

$$\bar{\mathbf{R}}_b = \text{Blockdiag}(\mathbf{R}_b, \mathbf{R}_b) = \begin{pmatrix} \mathbf{R}_b & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_b \end{pmatrix} \in \mathbb{R}^{6 \times 6}.$$

Then, substituting $\mathbf{P}_i^T \mathbf{v}$ from (38.2) into (38.32) yields the partial grasp matrix $\bar{\mathbf{G}}_i^T \in \mathbb{R}^{6 \times 6}$, that maps the object twist from $\{\mathbf{N}\}$ to contact frame $\{\mathbf{C}\}_i$ referred to $\{\mathbf{B}\}$.

Similarly, the hand twists can be expressed to the object frame $\{\mathbf{B}\}$

$$\mathbf{v}_{i,\text{hnd}} = \bar{\mathbf{R}}_b^T \begin{pmatrix} \mathbf{v}_{i,\text{hnd}}^N \\ \boldsymbol{\omega}_{i,\text{hnd}}^N \end{pmatrix} \quad (38.33)$$

and combining (38.33) and (38.7) yields the partial hand Jacobian $\bar{\mathbf{J}}_i \in \mathbb{R}^{6 \times n_q}$, which relates the joint velocities to the contact twists on the hand expressed with respect to $\{\mathbf{B}\}$.

Table 38.7 gives the definitions of the selection matrices for the three contact models when object and hand twists are referred to frame $\{\mathbf{B}\}$. In the planar case, as far as contact constraint is concerned, equation (38.15) holds with \mathbf{H}_{iF} and \mathbf{H}_{iM} defined in Table 38.8.

The contact force variation $\Delta \boldsymbol{\lambda}$ from the equilibrium configuration is then related to the relative displacement between the object and the fingers at the contact points as

$$\mathbf{C}_c \Delta \boldsymbol{\lambda} = (\mathbf{J} \Delta \mathbf{q} - \mathbf{G}^T \Delta \mathbf{u}). \quad (38.34)$$

Table 38.7 Selection matrices for three contact models, when the object twists are expressed with respect to $\{\mathbf{B}\}$

Model	$n_{\lambda i}$	\mathbf{H}_{iF}	\mathbf{H}_{iM}
PwoF	1	$\hat{\mathbf{n}}_i^{bT}$	Vacuous

By assuming that the perturbed configuration is sufficiently near to the reference one, the following linearized relationships can be found for \mathbf{g} , and $\boldsymbol{\tau}$

$$\Delta \mathbf{g} = -\mathbf{G} \Delta \boldsymbol{\lambda} \quad (38.35)$$

$$\Delta \boldsymbol{\tau} = \mathbf{J}^T \Delta \boldsymbol{\lambda} + \mathbf{K}_{J,q} \Delta \mathbf{q} + \mathbf{K}_{J,u} \Delta \mathbf{u} \quad (38.36)$$

where

$$\mathbf{K}_{J,q} = \frac{\partial \mathbf{J} \boldsymbol{\lambda}_0}{\partial \mathbf{q}} \quad \text{and} \quad \mathbf{K}_{J,u} = \frac{\partial \mathbf{J} \boldsymbol{\lambda}_0}{\partial \mathbf{u}}$$

are the variation of the hand Jacobian with respect to \mathbf{q} and \mathbf{u} variations, respectively.

Remark 38.3

In (38.35) and (38.36) both the grasp matrix and hand Jacobian are expressed with respect to the object reference frame, and by neglecting rolling between the fingers and the object at the contact points, \mathbf{G} becomes constant, while $\mathbf{J}(\mathbf{q}, \mathbf{u})$, in general, depends on both hand and object configurations. Matrix $\mathbf{K}_{J,q}$ represent the variability of $\mathbf{J}(\mathbf{q}, \mathbf{u})$ matrix with respect to hand and object configurations.

Matrices $\mathbf{K}_{J,q} \in \mathbb{R}^{n_q \times n_q}$ and $\mathbf{K}_{J,u} \in \mathbb{R}^{n_q \times n_v}$ are usually referred to as *geometric stiffness matrices* [38.28]. Furthermore, it can be verified that the matrix $\mathbf{K}_{J,q}$ is symmetric [38.27].

By substituting (38.36) in (38.30) we get

$$\mathbf{J}_R \mathbf{C}_q \mathbf{J}^T \Delta \boldsymbol{\lambda} = \mathbf{J}_R \Delta \mathbf{q}_r - \mathbf{J} \Delta \mathbf{q} - \mathbf{J}_R \mathbf{C}_q \mathbf{K}_{J,u} \Delta \mathbf{u}, \quad (38.37)$$

where

$$\mathbf{J}_R = \mathbf{J} (\mathbf{I} + \mathbf{C}_q \mathbf{K}_{J,q})^{-1}.$$

Summing (38.34) and (38.37) the following expression can be found for the contact forces displacement $\Delta\lambda$

$$\Delta\lambda = \mathbf{K}_{c,e} (\mathbf{J}_R \Delta\mathbf{q}_r - \mathbf{G}_R^T \Delta\mathbf{u}) \quad (38.38)$$

where

$$\mathbf{G}_R^T = \mathbf{G}^T + \mathbf{J}_R \mathbf{C}_q \mathbf{K}_{J,u}$$

and

$$\mathbf{K}_{c,e} = (\mathbf{C}_c + \mathbf{J}_R \mathbf{C}_q \mathbf{J}^T)^{-1}. \quad (38.39)$$

Matrix $\mathbf{K}_{c,e}$ represents the equivalent contact stiffness, that takes into account both the joint and the contact compliance. If the geometrical terms are neglected, i. e., $\mathbf{K}_{J,q} = 0$ and $\mathbf{K}_{J,u} = 0$, the classical expression $\mathbf{K}_{c,e} = (\mathbf{C}_c + \mathbf{J} \mathbf{C}_q \mathbf{J}^T)^{-1}$ for the equivalent contact stiffness matrix can be found [38.28].

By substituting (38.38) in (38.35), the object displacement can be evaluated as a function of the small input perturbations $\Delta\mathbf{q}_r$ and $\Delta\mathbf{g}$

$$\Delta\mathbf{u} = (\mathbf{G} \mathbf{K}_{c,e} \mathbf{G}_R^T)^{-1} (\mathbf{G} \mathbf{K}_{c,e} \mathbf{J}_R \Delta\mathbf{q}_r + \Delta\mathbf{g}). \quad (38.40)$$

When $\Delta\mathbf{q}_r = 0$, (38.40) can be rewritten as

$$\Delta\mathbf{g} = \mathbf{K} \Delta\mathbf{u},$$

$$\text{with } \mathbf{K} = \mathbf{G} \mathbf{K}_{c,e} \mathbf{G}_R^T,$$

where the term that multiplies the external wrench variation $\Delta\mathbf{g}$ represents the reciprocal of the *grasp stiffness matrix* \mathbf{K} . The grasp stiffness evaluates ability of the

robotic grasp to resist to external load variations applied to the object.

Regarding the force distribution $\Delta\lambda$, by substituting (38.40) into (38.38), the variation of the contact forces is evaluated as

$$\Delta\lambda = \mathbf{G}_g^+ \Delta\mathbf{g} + \mathbf{P} \Delta\mathbf{q}_r, \quad (38.41)$$

where

$$\mathbf{G}_g^+ = \mathbf{K}_{c,e} \mathbf{G}_R^T (\mathbf{G} \mathbf{K}_{c,e} \mathbf{G}_R^T)^{-1},$$

$$\mathbf{P} = (\mathbf{I} - \mathbf{G}_g^+ \mathbf{G}) \mathbf{K}_{c,e} \mathbf{J}_R.$$

Matrix \mathbf{G}_g^+ is a right pseudo-inverse of grasp matrix \mathbf{G} that takes into account both the geometrical effects and the hand and contact stiffness. Matrix \mathbf{P} maps the reference joint variables $\Delta\mathbf{q}_r$ to the contact force variation $\Delta\lambda$.

It is worth noting that $(\mathbf{I} - \mathbf{G}_g^+ \mathbf{G})$ is a projector onto the null space of \mathbf{G} and then each contact force variation $\Delta\lambda_h = \mathbf{P} \Delta\mathbf{q}_r$, produced by modifying joint reference values, satisfies the equation

$$\mathbf{G} \Delta\lambda_h = 0,$$

and then belongs to the internal force subspace.

Summarizing, compliant grasps have been analyzed with a linearized quasi-static model and the main relationships mapping joint references, the controlled inputs, and external disturbances, the wrenches, onto object motions and contact forces have been evaluated in (38.40) and (38.41), respectively.

38.4 Restraint Analysis

The most fundamental requirements in grasping and dexterous manipulation are the abilities to hold an object and control its position and orientation relative to the palm of the hand. The two most useful characterizations of grasp restraint are *force closure* and *form closure*. These names were in use as early as 1876 in the field of machine design to distinguish between joints that required an external force to maintain contact, and those that did not [38.31]. For example, some water wheels had a cylindrical axle that was laid in a horizontal semi-cylindrical groove split on either side of the wheel. During operation, the weight of the wheel acted to *close* the groove-axle contacts, hence the term *force closure*. By contrast, if the grooves were replaced by cylindrical holes just long enough to accept the axle, then the contacts would be closed by the geometry (even if the direction of the gravitational force was reversed), hence the term *form closure*.

When applied to grasping, form and force closure have the following interpretations. Assume that a hand grasping an object has its joint angles locked and its palm fixed in space. Then the grasp has *form closure*, or the object is *form-closed*, if it is impossible to move the object, even infinitesimally. Under the same conditions, the grasp has *force closure*, or the object is *force-closed*, if for any non-contact wrench experienced by the object, contact wrench intensities exist that satisfy (38.20) and are consistent with the constraints imposed by the friction models applicable at the contact points. Notice that all form closure grasps are also force closure grasps. When under form closure, the object cannot move even infinitesimally relative to the hand, regardless of the non-contact wrench. Therefore, the hand maintains the object in equilibrium for any external wrench, which is the force closure requirement.

Roughly speaking, form closure occurs when the palm and fingers wrap around the object forming a cage with no *wiggle room* such as the grasp shown in Fig. 38.6. This kind of grasp is also called a *power grasp* [38.32] or *enveloping grasp* [38.33]. However, force closure is possible with fewer contacts, as shown in Fig. 38.7, but in this case, force closure requires the ability to control internal forces. It is also possible for a grasp to have partial form closure, indicating that

Fig. 38.6 The palm and fingers combine to create a very secure form closure grasp of a router

Fig. 38.7 Hand and wrist of the tendon driven DLR Hand Arm System grasping a tool [38.7]. This grasp has a force closure grasp appropriate for dexterous manipulation. (DLR Hand Arm System, Photo courtesy of DLR 2011)

only a subset of the possible degrees of freedom are restrained [38.34]. An example of such a grasp is shown in Fig. 38.8. In this grasp, fingertip placement between the ridges around the periphery of the bottle cap provides form closure against relative rotation about the axis of the helix of the threads and also against translation perpendicular to that axis, but the other three degrees of freedom are restrained through force closure. Strictly speaking, given a grasp of a real object by a human hand it is impossible to prevent relative motion of the object with respect to the palm due to the compliance of the hand and object. Preventing all motion is possible only if the contacting bodies are rigid, as is assumed in most mathematical models employed in grasp analysis.

38.4.1 Form Closure

To make the notion of form closure precise, introduce a signed gap function denoted by $\psi_i(\mathbf{u}, \mathbf{q})$ at each of the n_c contact points between the object and the hand. The gap function is zero at each contact, becomes positive if contact breaks, and negative if penetration occurs. The gap function can be thought of as distance between the contact points. In general, this function is dependent on the shapes of the contacting bodies. Let $\bar{\mathbf{u}}$ and $\bar{\mathbf{q}}$ represent the configurations of the object and hand for a given grasp; then

$$\psi_i(\bar{\mathbf{u}}, \bar{\mathbf{q}}) = 0 \quad \forall i = 1, \dots, n_c. \quad (38.42)$$

The form closure condition can now be stated in terms of a differential change $d\mathbf{u}$ of $\bar{\mathbf{u}}$:

Fig. 38.8 In the grasp depicted, contact with the ridges on the bottle cap create partial form closure in the direction of cap rotation (when screwing it in) and also in the directions of translation perpendicular to the axis of rotation. To achieve complete control over the cap, the grasp achieves force closure over the other three degrees of freedom

Definition 38.6

A grasp $(\bar{\mathbf{u}}, \bar{\mathbf{q}})$ has *form closure* if and only if the following implication holds

$$\boldsymbol{\psi}(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}}) \geq \mathbf{0} \Rightarrow d\mathbf{u} = \mathbf{0}, \quad (38.43)$$

where $\boldsymbol{\psi}$ is the n_c -dimensional vector of gap functions with i -th component equal to $\psi_i(\mathbf{u}, \mathbf{q})$. By definition, inequalities between vectors imply that the inequality is applied between corresponding components of the vectors.

Expanding the gap function vector in a Taylor series about $\bar{\mathbf{u}}$, yields infinitesimal form closure tests of various orders. Let ${}^\beta \boldsymbol{\psi}(\mathbf{u}, \mathbf{q})$, $\beta = 1, 2, 3, \dots$, denote the Taylor series approximation truncated after the terms of order β in $d\mathbf{u}$. From (38.42), it follows that the first-order approximation is

$${}^1 \boldsymbol{\psi}(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}}) = \frac{\partial \boldsymbol{\psi}(\mathbf{u}, \mathbf{q})}{\partial \mathbf{u}} \Big|_{(\bar{\mathbf{u}}, \bar{\mathbf{q}})} d\mathbf{u},$$

where $\frac{\partial \boldsymbol{\psi}(\mathbf{u}, \mathbf{q})}{\partial \mathbf{u}} \Big|_{(\bar{\mathbf{u}}, \bar{\mathbf{q}})}$ denotes the partial derivative of $\boldsymbol{\psi}$ with respect to \mathbf{u} evaluated at $(\bar{\mathbf{u}}, \bar{\mathbf{q}})$. Replacing $\boldsymbol{\psi}$ with its approximation of order β in (38.43) implies three relevant cases of order β :

1. If there exists $d\mathbf{u}$ such that ${}^\beta \boldsymbol{\psi}(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}})$ has at least one strictly positive component, then the grasp does not have form closure of order β .
2. If for every non-zero $d\mathbf{u}$, ${}^\beta \boldsymbol{\psi}(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}})$ has at least one strictly negative component, then the grasp has form closure of order β .
3. If neither case i) nor case ii) applies for all ${}^\eta \boldsymbol{\psi}(\bar{\mathbf{u}} + d\mathbf{u}, \bar{\mathbf{q}}) \forall \eta \leq \beta$, then higher-order analysis is required to determine the existence of form closure.

Figure 38.9 illustrates form closure concepts using several planar grasps of gray objects by fingers shown as black disks. The concepts are identical for grasps of three-dimensional objects, but are more clearly illustrated in the plane. The grasp on the left has first-order

Fig. 38.9 Three planar grasps; two with form closure of different orders and one without form closure

form closure. Note that first-order form closure only involves the first derivatives of the distance functions. This implies that the only relevant geometry in first-order form closure are the locations of the contacts and the directions of the contact normals. The grasp in the center has form closure of higher order, with the specific order depending on the degrees of the curves defining the surfaces of the object and fingers in the neighborhoods of the contacts [38.35]. Second-order form closure analysis depends on the curvatures of the two contacting bodies in addition to the geometric information used to analyze first-order form closure. The grasp on the right does not have form closure of any order, because the object can translate horizontally and rotate about its center.

First-Order Form Closure

First-order form closure exists if and only if the following implication holds

$$\frac{\partial \boldsymbol{\psi}(\mathbf{u}, \mathbf{q})}{\partial \mathbf{u}} \Big|_{(\bar{\mathbf{u}}, \bar{\mathbf{q}})} d\mathbf{u} \geq \mathbf{0} \Rightarrow d\mathbf{u} = \mathbf{0}.$$

The first-order form closure condition can be written in terms of the object twist \mathbf{v}

$$\mathbf{G}_n^T \mathbf{v} \geq \mathbf{0} \Rightarrow \mathbf{v} = \mathbf{0}, \quad (38.44)$$

where $\mathbf{G}_n^T = \partial \boldsymbol{\psi} / \partial \mathbf{u} \mathbf{V} \in \mathbb{R}^{n_c \times 6}$. Recall that \mathbf{V} is the kinematic map defined in (38.1). Also notice that \mathbf{G}_n is the grasp matrix, when all contact points are frictionless.

Because the gap functions only quantify distances, the product $\mathbf{G}_n^T \mathbf{v}$ is the vector of normal components of the instantaneous velocities of the object at the contact points (which must be non-negative to prevent interpenetration). This in turn implies that the grasp matrix is the one that would result from the assumption that all contacts are of the type Pwof.

An equivalent condition in terms of the contact wrench intensity vector $\boldsymbol{\lambda}_n \in \mathbb{R}^{n_c}$ can be stated as follows. A grasp has first-order form closure if and only if

$$\left. \begin{array}{l} \mathbf{G}_n \boldsymbol{\lambda}_n = -\mathbf{g} \\ \boldsymbol{\lambda}_n \geq \mathbf{0} \end{array} \right\} \forall \mathbf{g} \in \mathbb{R}^6. \quad (38.45)$$

The physical interpretation of this condition is that equilibrium can be maintained under the assumption that the contacts are frictionless. Note that the components of $\boldsymbol{\lambda}_n$ are the magnitudes of the normal components of the contact forces. The subscript $(\cdot)_n$ is used to emphasize that $\boldsymbol{\lambda}_n$ contains no other force or moment components.

Since \mathbf{g} must be in the range of \mathbf{G}_n for equilibrium to be satisfied, and since \mathbf{g} is an arbitrary element of \mathbb{R}^6 , then in order for condition (38.45) to be satisfied, the rank of \mathbf{G}_n must be six. Assuming $\text{rank}(\mathbf{G}_n) = 6$, another equivalent mathematical statement of first-order form closure is: there exists λ_n such that the following two conditions hold [38.36]

$$\begin{aligned}\mathbf{G}_n \lambda_n &= \mathbf{0}, \\ \lambda_n &> \mathbf{0}.\end{aligned}\quad (38.46)$$

This means that there exists a set of strictly compressive normal contact forces in the null space of \mathbf{G}_n . In other words, one can squeeze the object as tightly as desired while maintaining equilibrium. A second interpretation of this condition is that the non-negative span of the columns of \mathbf{G}_n must equal \mathbb{R}^6 . Equivalently, the convex hull of the columns of \mathbf{G}_n must strictly contain the origin of \mathbb{R}^6 . As will be seen, the span and hull interpretations will provide a conceptual link called *frictional form closure* that lies between form closure and force closure.

The duality of conditions (38.44) and (38.45) can be seen clearly by examining the set of wrenches that can be applied by frictionless contacts and the corresponding set of possible object twists. For this discussion, it is useful to give definitions of cones and their duals.

Definition 38.7

A *cone* C is a set of vectors $\boldsymbol{\zeta}$ such that for every $\boldsymbol{\zeta}$ in C , every non-negative scalar multiple of $\boldsymbol{\zeta}$ is also in C .

Equivalently, a cone is a set of vectors closed under addition and non-negative scalar multiplication.

Definition 38.8

Given a cone C with elements $\boldsymbol{\zeta}$, the *dual cone* C^* with elements $\boldsymbol{\zeta}^*$, is the set of vectors such that the dot product of $\boldsymbol{\zeta}^*$ with each vector in C is non-negative. Mathematically

$$C^* = \{\boldsymbol{\zeta}^* | \boldsymbol{\zeta}^T \boldsymbol{\zeta}^* \geq 0, \forall \boldsymbol{\zeta} \in C\}.\quad (38.47)$$

See Example 4.

First-Order Form Closure Requirements

Several useful necessary conditions for form closure are known. In 1897 *Somov* proved that at least seven contacts are necessary to form close a rigid object with six degrees of freedom [38.37, 38]. *Lakshminarayana* generalized this to prove that $n_v + 1$ contacts are necessary to form close an object with n_v degrees

of freedom [38.34] (based on *Goldman* and *Tucker* 1956 [38.39]) (Table 38.9). This led to the definition of partial form closure that was mentioned above in the discussion of the hand grasping the bottle cap. *Markenscoff* and *Papadimitriou* determined a tight upper bound, showing that for all objects whose surfaces are not surfaces of revolution, at most $n_v + 1$ contacts are necessary [38.40]. Form closure is impossible to achieve for surfaces of revolution.

To emphasize the fact that $n_v + 1$ contacts are necessary and *not* sufficient, consider grasping a cube with seven or more points of contact. If all contacts are on one face, then clearly, the grasp does not have form closure.

First-Order Form Closure Tests

Because form closure grasps are very secure, it is desirable to design or synthesize such grasps. To do this, one needs a way to test candidate grasps for form closure, and rank them, so that the *best* grasp can be chosen. One reasonable measure of form closure can be derived from the geometric interpretation of the condition (38.46). The null space constraint and the positivity of λ_n represent the addition of the columns of \mathbf{G}_n scaled by the components of λ_n . Any choice of λ_n closing this loop is in $\mathcal{N}(\mathbf{G}_n)$. For a given loop, if the magnitude of the smallest component of λ_n is positive, then the grasp has form closure, otherwise it does not. Let us denote this smallest component by d . Since such a loop, and hence d , can be scaled arbitrarily, λ_n must be bounded.

After verifying that \mathbf{G}_n has full row rank, a quantitative form closure test based on the above observations can be formulated as a linear program (LP) in the unknowns d and λ_n as follows

$$\text{LP1:} \quad \text{maximize:} \quad d \quad (38.48)$$

$$\text{subject to:} \quad \mathbf{G}_n \lambda_n = \mathbf{0} \quad (38.49)$$

$$\mathbf{I} \lambda_n - \mathbf{1}d \geq \mathbf{0} \quad (38.50)$$

$$d \geq 0 \quad (38.51)$$

$$\mathbf{1}^T \lambda_n \leq n_c, \quad (38.52)$$

where $\mathbf{I} \in \mathbb{R}^{n_c \times n_c}$ is the identity matrix and $\mathbf{1} \in \mathbb{R}^{n_c}$ is a vector with all components equal to 1. The last inequality is designed to prevent this LP from becoming unbounded. A typical LP solution algorithm determines

Table 38.9 Minimum number of contacts n_c required to form close an object with n_v degrees of freedom

n_v	n_c
3 (planar grasp)	4
6 (spatial grasp)	7
n_v (general)	$n_v + 1$

infeasibility or unboundedness of the constraints in Phase I of the algorithm, and considers the result before attempting to calculate an optimal value [38.41]. If LP1 is infeasible, or if the optimal value d^* is zero, then the grasp is not form closed.

The quantitative form closure test (38.48)–(38.52) has $n_c + 8$ constraints and $n_c + 1$ unknowns. For a typical grasp with $n_c < 10$, this is a small linear program that can be solved very quickly using the simplex method. However, one should note that d^* is dependent on the choice of units used when forming \mathbf{G}_n . It would be advisable to non-dimensionalize the components of the wrenches to avoid dependence of the optimal d on one's choice of units. This could be done by dividing the first three rows of \mathbf{G}_n by a characteristic force and the last three rows by a characteristic moment. If one desires a binary test, LP1 can be converted into one by dropping the last constraint (38.52) and applying only Phase I of the simplex algorithm.

In summary, quantitative form closure testing is a two-step process:

Form Closure Test.

1. Compute $\text{rank}(\mathbf{G}_n)$.
 - a) If $\text{rank}(\mathbf{G}_n) \neq n_v$, then form closure does not exist. Stop.
 - b) If $\text{rank}(\mathbf{G}_n) = n_v$, continue.
2. Solve LP1.
 - a) If $d^* = 0$, then form closure does not exist.
 - b) If $d^* > 0$, then form closure exists and $d^* n_c$ is a crude measure of how far the grasp is from losing form closure.

See Example 5, Part 1.

Variations of the Test. If the rank test fails, then the grasp could have partial form closure over as many as $\text{rank}(\mathbf{G}_n)$ degrees of freedom. If one desires to test this, then LP1 must be solved using a new \mathbf{G}_n formed by retaining only the rows corresponding to the degrees of freedom for which partial form closure is to be tested. If $d^* > 0$, then partial form closure exists.

A second variation arises when one knows in advance that the object is already partially constrained. For example, in the case of a steering wheel, the driver knows, that relative to her, the steering wheel has only one degree of freedom. A form closure grasp suitable for driving would be required only to restraint the wheel's rotation about the steering column. In general, assume that the object is constrained by a set of bilateral constraints, which can be written as

$$\mathbf{B}^T \mathbf{v} = \mathbf{0}. \quad (38.53)$$

With these additional constraints, the form closure property can be expressed as follows

$$\left. \begin{array}{l} \mathbf{G}_n^T \mathbf{v} \geq \mathbf{0} \\ \mathbf{B}^T \mathbf{v} = \mathbf{0} \end{array} \right\} \Rightarrow \mathbf{v} = \mathbf{0}, \quad (38.54)$$

which can be shown to be equivalent to

$$\overline{\mathbf{G}}_n^T \boldsymbol{\rho} \geq \mathbf{0} \Rightarrow \boldsymbol{\rho} = \mathbf{0}, \quad (38.55)$$

where $\boldsymbol{\rho}$ is an arbitrary vector with length equal to the dimension of the null space of \mathbf{B}^T and $\overline{\mathbf{G}}_n = \mathbf{A}_B \mathbf{G}_n$, where \mathbf{A}_B is an annihilator of the column space of \mathbf{B} . One possible way to construct this annihilator is $\mathbf{A}_B = (\mathbf{N}(\mathbf{B}^T))^T$, where $\mathbf{N}(\mathbf{B}^T)$ is a matrix whose columns form a basis for the null space of \mathbf{B}^T . Also note that $\mathbf{N}(\mathbf{B}^T)\boldsymbol{\rho}$ is a possible twist of the object consistent with the bilateral constraints (i.e., the twists that must be eliminated by the unilateral constraints).

The form closure condition for an object partially constrained by bilateral constraints can also be stated in terms of wrenches

$$\left. \begin{array}{l} \overline{\mathbf{G}}_n \boldsymbol{\lambda}_n = \mathbf{0}, \\ \boldsymbol{\lambda}_n > \mathbf{0}. \end{array} \right\} \quad (38.56)$$

Notice that twist conditions (38.44) and (38.55) and wrench conditions (38.46) and (38.56) are formally analogous, and therefore, the quantitative form closure test can be applied by substituting $\overline{\mathbf{G}}_n$ for \mathbf{G}_n and $(n_v - \text{rank}(\mathbf{B}))$ for n_v . For detailed information on the derivations of the constrained form closure conditions, please refer to [38.42].

See Example 5, Part 2.

Monotonicity. In grasp synthesis, sometimes it is desirable for the grasp metric to increase monotonically with the number of contact points, the intuition being, that adding contacts to a stable grasp will make it more stable. The solution d^* does not have this property. However `formClosure.m`, a Matlab function which is available at [38.43], returns $d^* n_c$ as the metric, because it nearly maintains monotonicity when adding random contacts to random grasps. This can be demonstrated by running `test_monotonicity.m`.

One can design metrics that are monotonic with norms on the set of wrenches that the hand can apply. Let the polytope $\mathcal{G} = \{\mathbf{g} | \mathbf{g} = \mathbf{G}_n \boldsymbol{\lambda}_n, \mathbf{0} \leq \boldsymbol{\lambda}_n \leq \mathbf{1}\}$ denote the wrench space, which is the set of wrenches that can be applied by the hand if the contact forces magnitudes are limited to one. A metric proposed by Ferrari and Canny [38.44] is the radius of the largest sphere in \mathcal{G} with origin at the origin of the wrench space. The radius is greater than 0 if and only if the grasp has form

closure. In addition, adding a contact point will always produce a new \mathcal{G} that is a superset of the original \mathcal{G} . Thus the radius of the sphere cannot reduce as a result. Hence the monotonicity property holds.

See Example 5, Part 3.

Planar Simplifications

In the planar case, *Nguyen* [38.45] developed a graphical qualitative test for form closure. Figure 38.10 shows a form closure grasp with four contacts. To test form closure one partitions the normals into two groups of two. Let C_1 be the non-negative span of two normals in one pair and C_2 be the non-negative span of the other pair. A grasp has form closure if and only if C_1 and C_2 or $-C_1$ and $-C_2$ see each other for any pairings. Two cones see each other if the open line segment defined by the vertices of the cones lies in the interior of both cones. In the presence of more than four contacts, if any set of four contacts satisfies this condition, then the grasp has form closure.

Notice that this graphical test can be difficult to execute for grasps with more than four contacts. Also, it does not extend to grasps of three-dimensional (3-D) objects and does not provide a closure measure.

38.4.2 Force Closure

A grasp has force closure, or is force-closed, if the grasp can be maintained in the face of any object wrench. Force closure is similar to form closure, but relaxed to allow friction forces to help balance the object wrench. A benefit of including friction in the analysis is the reduction in the number of contact points needed for closure. A three-dimensional object with six degrees of freedom requires seven contacts for form closure, but for force closure, only two contacts are needed if they are modeled as soft fingers, and only three (non-collinear) contacts are needed if they are modeled as hard fingers.

Force closure relies on the ability of the hand to squeeze arbitrarily tightly in order to compensate for large applied wrenches that can only be resisted by friction. Figure 38.15 shows a grasped polygon. Con-

sider applying a wrench to the object that is a pure force acting upward along the y -axis of the inertial frame. It seems intuitive that if there is enough friction, the hand will be able to squeeze the object with friction forces preventing the object's upward escape. Also, as the applied force increases in magnitude, the magnitude of the squeezing force will have to increase accordingly.

Since force closure is dependent on the friction models, common models will be introduced before giving formal definitions of force closure.

Friction Models

Recall the components of force and moment transmitted through contact i under the various contact models given earlier in Table 38.4. At contact point i , the friction law imposes constraints on the components of the contact force and moment. Specifically, the frictional components of λ_i are constrained to lie inside a limit surface, denoted by \mathcal{L}_i , that scales linearly with the product $\mu_i f_{in}$, where μ_i is the coefficient of friction at contact i . In the case of Coulomb friction, the limit surface is a circle of radius $\mu_i f_{in}$. The Coulomb friction cone \mathcal{F}_i is a subset of \mathbb{R}^3

$$\mathcal{F}_i = \{(f_{in}, f_{it}, f_{io}) \mid \sqrt{f_{it}^2 + f_{io}^2} \leq \mu_i f_{in}\}. \quad (38.57)$$

More generally, the friction laws of interest have limit surfaces defined in the space of friction components, $\mathbb{R}^{n_{\lambda i}-1}$ and friction cones \mathcal{F}_i defined in the space of λ_i , $\mathbb{R}^{n_{\lambda i}}$. They can be written as follows

$$\mathcal{F}_i = \{\lambda_i \in \mathbb{R}^{n_{\lambda i}} \mid \|\lambda_i\|_w \leq f_{in}\}, \quad (38.58)$$

where $\|\lambda_i\|_w$ denotes a weighted quadratic norm of the friction components at contact i . The limit surface is defined by $\|\lambda_i\|_w = f_{in}$.

Table 38.10 defines useful weighted quadratic norms for the three contact models: **PwoF**, **HF**, and **SF**. The parameter μ_i is the friction coefficient for the tangential forces, v_i is the torsional friction coefficient, and a is the characteristic length of the object that is used to ensure consistent units for the norm of the **SF** model.

Table 38.10 Norms for the three main contact models

Model	$\ \lambda_i\ _w$
PwoF	0
HF	$\frac{1}{\mu_i} \sqrt{f_{it}^2 + f_{io}^2}$
SF	$\frac{1}{\mu_i} \sqrt{f_{it}^2 + f_{io}^2} + \frac{1}{a v_i} m_{in} $

Fig. 38.10 Planar grasps with first-order form closure

Remark 38.4

There are several noteworthy points to be made about the friction cones. First, all of them implicitly or explicitly constrain the normal component of the contact force to be non-negative. The cone for **SF** contacts has a cylindrical limit surface with circular cross section in the (f_{it}, f_{io}) -plane and rectangular cross section in the (f_{it}, m_{in}) -plane. With this model, the amount of torsional friction that can be transmitted is independent of the lateral friction load. An improved model that couples the torsional friction limit with the tangential limit was studied by *Howe and Cutkosky* [38.46].

A Force Closure Definition

One common definition of force closure can be stated simply by modifying condition (38.45) to allow each contact force to lie in its friction cone rather than along the contact normal. Because this definition does not consider the hand's ability to control contact forces, this definition will be referred to as *frictional form closure*. A grasp will be said to have frictional form closure if and only if the following condition is satisfied

$$\begin{aligned} \mathbf{G}\boldsymbol{\lambda} &= -\mathbf{g} \\ \boldsymbol{\lambda} &\in \mathcal{F} \end{aligned} \quad \forall \mathbf{g} \in \mathbb{R}^{n_v},$$

where \mathcal{F} is the composite friction cone defined as:

$$\begin{aligned} \mathcal{F} &= \mathcal{F}_1 \times \cdots \times \mathcal{F}_{n_c} \\ &= \{\boldsymbol{\lambda} \in \mathbb{R}^m \mid \lambda_i \in \mathcal{F}_i; i = 1, \dots, n_c\}, \end{aligned}$$

and each \mathcal{F}_i is defined by (38.58) and one of the models listed in Table 38.10.

Letting $\text{Int}(\mathcal{F})$ denote the interior of the composite friction cone, *Murray et al.* give the following equivalent definition [38.19]:

Definition 38.9

(Proposition 5.2, *Murray et al.*) A grasp has *frictional form closure* if and only if the following conditions are satisfied:

1. $\text{rank}(\mathbf{G}) = n_v$
2. $\exists \boldsymbol{\lambda}$ such that $\mathbf{G}\boldsymbol{\lambda} = \mathbf{0}$ and $\boldsymbol{\lambda} \in \text{Int}(\mathcal{F})$.

These conditions define what *Murray et al.* call *force closure*. The force closure definition adopted here is stricter than frictional form closure; it additionally requires that the hand be able to control the internal object forces.

Definition 38.10

A grasp has *force closure* if and only if

$$\text{rank}(\mathbf{G}) = n_v, \quad \mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^T) = \mathbf{0},$$

and there exists $\boldsymbol{\lambda}$ such that $\mathbf{G}\boldsymbol{\lambda} = \mathbf{0}$ and $\boldsymbol{\lambda} \in \text{Int}(\mathcal{F})$.

The full row rank condition on the matrix \mathbf{G} is the same condition required for form closure, although \mathbf{G} is different from \mathbf{G}_n used to determine form closure. If the rank test passes, then one must still find $\boldsymbol{\lambda}$ satisfying the remaining three conditions. Of these, the null space intersection test can be performed easily by linear programming techniques, but the friction cone constraint is quadratic, and thus forces one to use non-linear programming techniques. While exact non-linear tests have been developed [38.47], only approximate tests will be presented here.

Approximate Force Closure Tests

Any of the friction cones discussed can be approximated as the non-negative span of a finite number n_g of generators s_{ij} of the friction cone. Given this, one can represent the set of applicable contact wrenches at contact i as follows

$$\mathbf{G}_i \boldsymbol{\lambda}_i = \mathbf{S}_i \boldsymbol{\sigma}_i, \quad \boldsymbol{\sigma}_i \geq \mathbf{0},$$

where $\mathbf{S}_i = [s_{i1} \cdots s_{in_g}]$ and $\boldsymbol{\sigma}_i$ is a vector of non-negative generator weights. If contact i is frictionless, then $n_g = 1$ and $\mathbf{S}_i = [\hat{\mathbf{n}}_i^T ((\mathbf{c}_i - \mathbf{p}) \times \hat{\mathbf{n}}_i)^T]^T$.

If contact i is of type **HF**, we represent the friction cone by the non-negative sum of uniformly spaced contact force generators (Fig. 38.11) whose non-negative span approximates the Coulomb cone with an inscribed regular polyhedral cone. This leads to the following def-

Fig. 38.11 Quadratic cone approximated as a polyhedral cone with seven generators

inition of \mathbf{S}_i

$$\mathbf{S}_i = \begin{pmatrix} \cdots & 1 & \cdots \\ \cdots & \mu_i \cos(2k\pi/n_g) & \cdots \\ \cdots & \mu_i \sin(2k\pi/n_g) & \cdots \end{pmatrix}, \quad (38.59)$$

where the index k varies from one to n_g . If one prefers to approximate the quadratic friction cone by a circumscribing polyhedral cone, one simply replaces μ_i in the above definition with $\mu_i / \cos(\pi/n_g)$.

The adjustment needed for the **SF** model is quite simple. Since the torsional friction in this model is decoupled from the tangential friction, its generators are given by $[1 \ 0 \ 0 \ \pm bv_i]^T$. Thus \mathbf{S}_i for the **SF** model is

$$\mathbf{S}_i = \left(\begin{array}{ccc|cc} \cdots & 1 & \cdots & 1 & 1 \\ \cdots & \mu_i \cos(2k\pi/n_g) & \cdots & 0 & 0 \\ \cdots & \mu_i \sin(2k\pi/n_g) & \cdots & 0 & 0 \\ \cdots & 0 & \cdots & bv_i & -bv_i \end{array} \right), \quad (38.60)$$

where b is the characteristic length used to unify units. The set of total contact wrenches that may be applied by the hand without violating the contact friction law at any contact can be written as

$$\mathbf{G}\boldsymbol{\lambda} = \mathbf{S}\boldsymbol{\sigma}, \quad \boldsymbol{\sigma} \geq \mathbf{0},$$

where

$$\mathbf{S} = (\mathbf{S}_1, \dots, \mathbf{S}_{n_g})$$

and

$$\boldsymbol{\sigma} = (\sigma_1^T \cdots \sigma_{n_g}^T)^T.$$

It is convenient to reformulate the friction constraints in a dual form

$$\mathbf{F}_i \boldsymbol{\lambda}_i \geq \mathbf{0}. \quad (38.61)$$

In this form, each row of \mathbf{F}_i is normal to a face formed by two adjacent generators of the approximate cone. For an **HF** contact, row i of \mathbf{F}_i can be computed as the cross product of \mathbf{s}_i and \mathbf{s}_{i+1} . In the case of an **SF** contact, the generators are of dimension four, so simple cross products will not suffice. However, general methods exist to perform the conversion from the generator form to the face normal form [38.39].

The face normal constraints for all contacts can be combined into the following compact form

$$\mathbf{F}\boldsymbol{\lambda} \geq \mathbf{0}, \quad (38.62)$$

where $\mathbf{F} = \text{Blockdiag}(\mathbf{F}_1, \dots, \mathbf{F}_{n_c})$.

Let $\mathbf{e}_i \in \mathbb{R}^{n_{\lambda i}}$ be the first row of \mathbf{H}_i . Further let

$$\mathbf{e} = [\mathbf{e}_1, \dots, \mathbf{e}_{n_c}] \in \mathbb{R}^{n_{\lambda}}$$

and let

$$\mathbf{E} = \text{Blockdiag}(\mathbf{e}_1, \dots, \mathbf{e}_{n_c}) \in \mathbb{R}^{n_{\lambda} \times n_c}.$$

The following linear program is a quantitative test for frictional form closure. The optimal objective function value d^* is a measure of the distance the contact forces are from the boundaries of their friction cones, and hence a crude measure of how far a grasp is from losing frictional form closure.

$$\begin{array}{ll} \text{LP2:} & \text{maximize:} \quad d \\ & \text{subject to:} \quad \mathbf{G}\boldsymbol{\lambda} = \mathbf{0} \\ & \quad \mathbf{F}\boldsymbol{\lambda} - \mathbf{1}d \geq \mathbf{0} \\ & \quad d \geq 0 \\ & \quad \mathbf{e}\boldsymbol{\lambda} \leq n_c. \end{array}$$

The last inequality in LP2 is simply the sum of the magnitudes of the normal components of the contact forces. After solving LP2, if $d^* = 0$ frictional form closure does not exist, but if $d^* > 0$, then it does.

If the grasp has frictional form closure, the last step to determine the existence of force closure is to verify the condition $\mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^T) = \mathbf{0}$. If it holds, then the grasp has force closure. This condition is easy to verify with another linear program LP3.

$$\begin{array}{ll} \text{LP3:} & \text{maximize:} \quad d \\ & \text{subject to:} \quad \mathbf{G}\boldsymbol{\lambda} = \mathbf{0} \\ & \quad \mathbf{J}^T \boldsymbol{\lambda} = \mathbf{0} \\ & \quad \mathbf{E}\boldsymbol{\lambda} - \mathbf{1}d \geq \mathbf{0} \\ & \quad d \geq 0 \\ & \quad \mathbf{e}\boldsymbol{\lambda} \leq n_c. \end{array}$$

In summary, force closure testing is a three-step process.

Approximate Force Closure Test.

1. Compute $\text{rank}(\mathbf{G})$.
 - a) If $\text{rank}(\mathbf{G}) \neq n_v$, then force closure does not exist. Stop.
 - b) If $\text{rank}(\mathbf{G}) = n_v$, continue.
2. Solve LP2: *Test frictional form closure*.
 - a) If $d^* = 0$, then frictional form closure does not exist. Stop.
 - b) If $d^* > 0$, then frictional form closure exists and d^* is a crude measure of how far the grasp is from losing frictional form closure.

3. Solve LP3: *Test control of internal force.*
- If $d^* > 0$, then force closure does not exist.
 - If $d^* = 0$, then force closure exists.

Variation of the Test. A variation of the approximate force closure test arises when the object is partially constrained with the bilateral constraints described by (38.53), in such a cases the definitions of frictional form closure becomes

$$\begin{aligned}\bar{\mathbf{G}}\boldsymbol{\lambda} &= \mathbf{0}, \\ \boldsymbol{\lambda} &\in \text{int}(\mathcal{F}),\end{aligned}\quad (38.63)$$

where $\bar{\mathbf{G}} = \mathbf{A}_B \mathbf{G}$, \mathbf{A}_B is an annihilator of the column space of \mathbf{B} . Similarly, the force closure condition can be stated as

$$\begin{aligned}\bar{\mathbf{G}}\boldsymbol{\lambda} &= \mathbf{0}, \\ \boldsymbol{\lambda} &\in \text{int}(\mathcal{F}), \\ \mathcal{N}(\bar{\mathbf{G}}) \cap \mathcal{N}(\mathbf{J}^T) &= \mathbf{0},\end{aligned}\quad (38.64)$$

Since the frictional form closure definition (38.63) is analogous to Definition 38.9 and the force closure definition (38.64) is analogous to Definition 38.10, the force closure test can be applied by substituting $\bar{\mathbf{G}}$ for

\mathbf{G} , provided that, $(n_v - \text{rank}(\mathbf{B}))$ is substituted for n_v . For detailed information on the derivation of these conditions, please refer to [38.42].

See Example 1, Part 6.

Planar Simplifications

In planar grasping systems, the approximate method described above is exact. This is because the SF models are meaningless, since rotations about the contact normal would cause motions out of the plane. With regard to the HF model, for planar problems, the quadratic friction cone becomes linear, with its cone represented exactly as

$$\mathbf{F}_i = \frac{1}{\sqrt{1 + \mu_i^2}} \begin{pmatrix} \mu_i & 1 \\ \mu_i & -1 \end{pmatrix}. \quad (38.65)$$

Nguyen's graphical form closure test can be applied to planar grasps with two frictional contacts [38.45]. The only change is that the four contact normals are replaced by the four generators of the two friction cones. However, the test can only determine frictional form closure, since it does not incorporate the additional information needed to determine force closure.

38.5 Examples

38.5.1 Example 1: Grasped Sphere

Part 1: $\tilde{\mathbf{G}}$ and $\tilde{\mathbf{J}}$

Figure 38.12 shows a planar projection of a three-dimensional sphere of radius r grasped by two fingers, which make two contacts at angles θ_1 and θ_2 . The frames $\{\mathbf{C}\}_1$ and $\{\mathbf{C}\}_2$ are oriented so that their $\hat{\mathbf{d}}$ -directions point out of the plane of the figure (as indicated by the small filled circles at the contact points). The axes of the frames $\{\mathbf{N}\}$ and $\{\mathbf{B}\}$ were chosen to be axis-aligned with coincident origins located at the center of the sphere. The z -axes are pointing out of the page. Observe that since the two joint axes of the left finger are perpendicular to the (x, y) -plane, it operates in that plane for all time. The other finger has three revolute joints. Because its first and second axes, $\hat{\mathbf{z}}_3$ and $\hat{\mathbf{z}}_4$, currently lie in the plane, rotation about $\hat{\mathbf{z}}_3$ will cause $\hat{\mathbf{z}}_4$ to attain an out-of-plane component and would cause the finger tip at contact 2 to leave the plane.

In the current configuration, the rotation matrix for the i -th contact frame is defined as follows

$$\mathbf{R}_i = \begin{pmatrix} -\cos(\theta_i) & \sin(\theta_i) & 0 \\ -\sin(\theta_i) & -\cos(\theta_i) & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (38.66)$$

The vector from the origin of $\{\mathbf{N}\}$ to the i -th contact point is given by

$$\mathbf{c}_i - \mathbf{p} = r \begin{pmatrix} \cos(\theta_i) & \sin(\theta_i) & 0 \end{pmatrix}^T. \quad (38.67)$$

Substituting into (38.3) and (38.6) yields the complete grasp matrix for contact i

$$\tilde{\mathbf{G}}_i = \left(\begin{array}{ccc|ccc} -c_i & s_i & 0 & & & \\ -s_i & -c_i & 0 & & & \\ 0 & 0 & 1 & & & \\ \hline 0 & 0 & rs_i & -c_i & s_i & 0 \\ 0 & 0 & -rc_i & -s_i & -c_i & 0 \\ 0 & -r & 0 & 0 & 0 & 1 \end{array} \right), \quad (38.68)$$

where $\mathbf{0} \in \mathbb{R}^{3 \times 3}$ is the zero matrix and c_i and s_i are abbreviations for $\cos(\theta_i)$ and $\sin(\theta_i)$, respectively. The complete grasp matrix is defined as: $\tilde{\mathbf{G}} = (\tilde{\mathbf{G}}_1 \tilde{\mathbf{G}}_2) \in \mathbb{R}^{6 \times 12}$.

The accuracy of this matrix can be verified by inspection, according to Remark 38.2. For example, the first column is the unit wrench of the unit contact normal; the first three components are the direction cosines

Construction of the hand Jacobian $\tilde{\mathbf{J}}_i$ for contact i requires knowledge of the joint axis directions and the origins of the frames fixed to the links of each finger. Figure 38.13 shows the hand in the same configuration as in Fig. 38.12, but with some additional data needed to construct the hand Jacobian. Assume that the origins of the joint frames lie in the plane of the figure. In the current configuration, the quantities of interest for contact 1, expressed in $\{\mathbf{C}\}_1$ are

$$\hat{\mathbf{z}}_1 = \hat{\mathbf{z}}_2 = \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}^T. \quad (38.71)$$

$$\hat{\mathbf{z}}_3 = (0 \quad 1 \quad 0)^T, \quad (38.74)$$

$$\hat{\mathbf{z}}_4(q_3) = \frac{\sqrt{2}}{2} \begin{pmatrix} -1 & 1 & 0 \end{pmatrix}^T, \quad (38.75)$$

$$\hat{\mathbf{z}}_5(q_3, q_4) = \begin{pmatrix} 0 & 0 & 1 \end{pmatrix}^T. \quad (38.76)$$

Generally all of the components of the $\mathbf{c}-\boldsymbol{\xi}$ and $\hat{\mathbf{z}}$ vectors (including the components that are zero in the current configuration), are functions of \mathbf{q} and \mathbf{u} . The dependencies of the $\hat{\mathbf{z}}$ vectors are shown explicitly.

Substituting into (38.14), (38.11) and (38.8) yields the complete hand Jacobian $\mathbf{J} \in \mathbb{R}^{12 \times 5}$

$$\tilde{\mathbf{J}} = \left(\begin{array}{cc|ccc} -l_1 & -l_3 & & & \\ l_2 & l_7 & & & \\ 0 & 0 & & & \\ 0 & 0 & & \mathbf{0} & \\ 0 & 0 & & & \\ 1 & 1 & & & \\ \hline & & 0 & 0 & 0 \\ & & 0 & 0 & l_6 \\ & & l_4 & \frac{\sqrt{2}}{2}(l_4 + l_5) & 0 \\ \mathbf{0} & & 0 & -\frac{\sqrt{2}}{2} & 0 \\ & & -1 & -\frac{\sqrt{2}}{2} & 0 \\ & & 0 & 0 & 1 \end{array} \right).$$

The horizontal dividing line partitions $\tilde{\mathbf{J}}$ into $\tilde{\mathbf{J}}_1$ (on top) and $\tilde{\mathbf{J}}_2$ (on the bottom). The columns correspond to joints 1 through 5. The block diagonal structure is a result of the fact that finger i directly affects only contact i .

Example 1, Part 2: G and J

Assume that the contacts in Fig. 38.12 are both of type SF. Then the selection matrix \mathbf{H} is given by

$$\mathbf{H} = \left(\begin{array}{cccccc|cccc} 1 & 0 & 0 & 0 & 0 & 0 & & & & \\ 0 & 1 & 0 & 0 & 0 & 0 & & & & \\ 0 & 0 & 1 & 0 & 0 & 0 & & & & \\ 0 & 0 & 0 & 1 & 0 & 0 & & & & \\ \hline & & & & & & 1 & 0 & 0 & 0 & 0 & 0 \\ & & & & & & 0 & 1 & 0 & 0 & 0 & 0 \\ & & & & & & 0 & 0 & 1 & 0 & 0 & 0 \\ & & & & & & 0 & 0 & 0 & 1 & 0 & 0 \end{array} \right),$$

Fig. 38.12 A sphere grasped by a two-fingered hand with 5 revolute joints

Fig. 38.13 Relevant data for the hand Jacobian in Fig. 38.12

thus the matrices $\mathbf{G}^T \in \mathbb{R}^{8 \times 6}$ and $\mathbf{J} \in \mathbb{R}^{8 \times 5}$ are constructed by removing rows 5, 6, 11, and 12 from $\tilde{\mathbf{G}}^T$ and $\tilde{\mathbf{J}}$

$$\mathbf{G}^T = \begin{pmatrix} -c_1 & -s_1 & 0 & 0 & 0 & 0 \\ s_1 & -c_1 & 0 & 0 & 0 & -r \\ 0 & 0 & 1 & r s_1 & -r c_1 & 0 \\ 0 & 0 & 0 & -c_1 & -s_1 & 0 \\ -c_2 & -s_2 & 0 & 0 & 0 & 0 \\ s_2 & -c_2 & 0 & 0 & 0 & -r \\ 0 & 0 & 1 & r s_2 & -r c_2 & 0 \\ 0 & 0 & 0 & -c_2 & -s_2 & 0 \end{pmatrix}, \quad (38.77)$$

$$\mathbf{J} = \left(\begin{array}{cc|ccc} -l_1 & -l_3 & & & & \\ l_2 & l_7 & & & & \\ 0 & 0 & & & & \\ 0 & 0 & & & & \\ \hline & & 0 & 0 & 0 & \\ & & 0 & 0 & l_6 & \\ \mathbf{0} & & l_4 & \frac{\sqrt{2}}{2}(l_4 + l_5) & 0 & \\ & & 0 & -\frac{\sqrt{2}}{2} & 0 & \end{array} \right). \quad (38.78)$$

Notice that changing the contact models is easily accomplished by removing more rows. Changing contact 1 to HF would eliminate the fourth rows from \mathbf{G}^T and \mathbf{J} . Changing it to PwoF would eliminate the second, third and fourth rows of \mathbf{G}^T and \mathbf{J} . Changing the model at contact 2 would remove either just the eighth row or the sixth, seventh, and eighth rows.

Example 1, Part 3: Reduce to Planar Case

The grasp shown in Fig. 38.12 can be reduced to a planar problem by following the explicit formulas given above, but it can also be done by understanding the physical interpretations of the various rows and columns of the matrices. Proceed by eliminating velocities and forces that are out of the plane. This can be done by removing the z -axes from $\{\mathbf{N}\}$ and $\{\mathbf{B}\}$, and the \hat{o} -directions at the contacts. Further, joints 3 and 4 must be locked. The resulting \mathbf{G}^T and \mathbf{J} are constructed eliminating certain rows and columns. \mathbf{G}^T is formed by removing rows 3, 4, 7, and 8 and columns 3, 4, and 5. \mathbf{J} is formed by removing rows 3, 4, 7, and 8 and columns 3 and 4 yielding

$$\mathbf{G}^T = \begin{pmatrix} -c_1 & -s_1 & 0 \\ s_1 & -c_1 & -r \\ -c_2 & -s_2 & 0 \\ s_2 & -c_2 & -r \end{pmatrix}, \quad (38.79)$$

$$\mathbf{J} = \begin{pmatrix} -l_1 & -l_3 & 0 \\ l_2 & l_7 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & l_6 \end{pmatrix}. \quad (38.80)$$

Example 1, Part 4: Grasp Classes

The first column of Table 38.11 reports the dimensions of the main subspaces of \mathbf{J} and \mathbf{G} for the sphere grasping example with different contact models. Only non-trivial null spaces are listed.

In the case of two HF contact models, all four null spaces are non-trivial, so the system satisfies the conditions for all four grasp classes. The system is graspable because there is an internal force along the line segment connecting the two contact points. Indeterminacy is manifested in the fact that the hand cannot resist a moment acting about that line. Redundancy is seen to exist since joint 3 can be used to move contact 2 out of the plane of the figure, but joint 4 can be rotated in the opposite direction to cancel this motion. Finally, the grasp is defective, because the contact forces and the instantaneous velocities along the \hat{o}_1 and \hat{n}_2 directions of contact 1 and 2, respectively, cannot be controlled through the joint torques and velocities. These interpretations are borne out in the null space basis matrices below, computed using $r = 1$, $\cos(\theta_1) = -0.8 = -\cos(\theta_2)$, $\sin(\theta_1) = \cos(\theta_2) = -0.6$, $l_1 = 3$, $l_2 = 2$, $l_3 = 1$, $l_4 = 2$, $l_5 = 1$, $l_6 = 1$, and $l_7 = 0$

$$\mathbf{N}(\mathbf{J}) \approx \begin{pmatrix} 0 \\ 0 \\ -0.73 \\ 0.69 \\ 0 \end{pmatrix}, \quad \mathbf{N}(\mathbf{G}^T) \approx \begin{pmatrix} 0 \\ 0 \\ 0.51 \\ 0.86 \\ 0 \\ 0 \end{pmatrix}, \quad (38.81)$$

$$\mathbf{N}(\mathbf{G}) \approx \begin{pmatrix} 0.57 \\ -0.42 \\ 0 \\ 0.57 \\ 0.42 \\ 0 \end{pmatrix}, \quad \mathbf{N}(\mathbf{J}^T) = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 0 & -1 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}. \quad (38.82)$$

Table 38.11 Dimensions of main subspaces and classifications of grasp studied in Example 1

Models	Dimension	Class
HF,HF	$\dim \mathcal{N}(\mathbf{J}) = 1$	Redundant
	$\dim \mathcal{N}(\mathbf{G}^T) = 1$	Indeterminate
	$\dim \mathcal{N}(\mathbf{G}) = 1$	Graspable
	$\dim \mathcal{N}(\mathbf{J}^T) = 2$	Defective
SF,HF	$\dim \mathcal{N}(\mathbf{J}) = 1$	Redundant
	$\dim \mathcal{N}(\mathbf{G}) = 1$	Graspable
	$\dim \mathcal{N}(\mathbf{J}^T) = 3$	Defective
HF,SF	$\dim \mathcal{N}(\mathbf{G}) = 1$	Graspable
	$\dim \mathcal{N}(\mathbf{J}^T) = 2$	Defective
SF,SF	$\dim \mathcal{N}(\mathbf{G}) = 2$	Graspable
	$\dim \mathcal{N}(\mathbf{J}^T) = 3$	Defective

Notice that changing either contact to **SF** makes it possible for the hand to resist external moments applied about the line containing the contacts, so the grasp loses indeterminacy, but retains graspability (with squeezing still possible along the line of the contacts). However, if contact 2 is the **SF** contact, the grasp loses its redundancy. While the second contact point can still be moved out of the plane by joint 3 and back in by joint 4, this canceled translation of the contact point yields a net rotation about \hat{n}_2 (this also implies that the hand can control the moment applied to the object along the line containing the contacts). Changing to **SF** at contact 2 does *not* affect the hand's inability to move contact 1 and contact 2 in the \hat{o}_1 and \hat{n}_2 directions, so the defectivity property is retained.

Example 1, Part 5: Desirable Properties

Assuming contact model types of **SF** and **HF** at contacts 1 and 2, respectively, \mathbf{G} is full row rank and so $\mathcal{N}(\mathbf{G}^T) = \mathbf{0}$ (see Table in part 4 of this example). Therefore, as long as the hand is sufficiently dexterous, it can apply any wrench in \mathbb{R}^6 to the object. Also, if the joints are locked, object motion will be prevented. Assuming the same problem values used in the previous part of this problem, the matrix \mathbf{G}^T is

$$\mathbf{G}^T = \begin{pmatrix} -c_1 & -s_1 & 0 & 0 & 0 & 0 \\ s_1 & -c_1 & 0 & 0 & 0 & -r \\ 0 & 0 & 1 & rs_1 & -rc_1 & 0 \\ 0 & 0 & 0 & -c_1 & -s_1 & 0 \\ -c_2 & -s_2 & 0 & 0 & 0 & 0 \\ s_2 & -c_2 & 0 & 0 & 0 & -r \\ 0 & 0 & 1 & rs_2 & -rc_2 & 0 \end{pmatrix} \quad (38.83)$$

Bases for the three non-trivial null spaces are

$$\mathbf{N}(\mathbf{J}^T) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad (38.84)$$

$$\mathbf{N}(\mathbf{J}) \approx \begin{pmatrix} 0 \\ 0 \\ -0.73 \\ 0.69 \\ 0 \end{pmatrix}, \quad \mathbf{N}(\mathbf{G}) \approx \begin{pmatrix} 0.57 \\ -0.42 \\ 0 \\ 0 \\ 0.57 \\ 0.42 \\ 0 \end{pmatrix}. \quad (38.85)$$

Since $\mathcal{R}(\mathbf{J})$ is four-dimensional and $\mathcal{N}(\mathbf{G})$ is one-dimensional, the maximum dimension of $\mathcal{R}(\mathbf{J}) + \mathcal{N}(\mathbf{G})$ cannot be more than 5, and therefore, the hand cannot control all possible object velocities. For example, the contact velocity $\mathbf{v}_{cc} = (0 \ 0 \ 0 \ 0.8 \ 0 \ 0)^T$ is in $\mathcal{N}(\mathbf{J}^T)$, and so cannot be controlled by the fingers. It is also equal to 0.6 times the third column of \mathbf{G}^T plus the 4th column of \mathbf{G}^T and therefore is in $\mathcal{R}(\mathbf{G}^T)$. Since the mapping between $\mathcal{R}(\mathbf{G})$ and $\mathcal{R}(\mathbf{G}^T)$ is one-to-one and onto, this uncontrollable contact velocity corresponds to a unique uncontrollable object velocity, $\mathbf{v} = (0 \ 0 \ 0.6 \ 1 \ 0 \ 0)$. In other words, the hand cannot cause the center of the sphere to translate in the z -direction, while also rotating about the x -axis (and not other axes simultaneously).

On the question of controlling all internal object forces, the answer is *yes*, since $\mathcal{N}(\mathbf{J}^T) \cap \mathcal{N}(\mathbf{G}) = \mathbf{0}$. This conclusion is clear from the fact that $\mathcal{N}(\mathbf{G})$ has non-zero values in the first, second, and sixth positions, while all columns of $\mathcal{N}(\mathbf{J}^T)$ have zeros in those positions.

Example 1, Part 6: Force Closure

Again assume that contacts 1 and 2 on the grasped sphere were modeled as **SF** and **HF** contacts, respectively. Under this assumption, \mathbf{G} is full row rank, and the internal force corresponds to equal and opposite contact forces. For frictional form closure to exist, the internal force must lie within the friction cones. Choosing r and the sines and cosines of θ_1 and θ_2 as in example 1, part 4, frictional form closure can be shown to exist if both friction coefficients are greater than 0.75. For this grasp, since $\mathcal{N}(\mathbf{J}^T) \cap \mathcal{N}(\mathbf{G}) = \mathbf{0}$, frictional form closure is equivalent to force closure.

The plot in Fig. 38.14 was generated by fixing μ_2 at a specific value and varying μ_1 from 0.5 to 2.0. Notice that for $\mu_1 < 0.75$, force closure does not exist regardless of the value of μ_2 . The metric increases smoothly until a specific value of μ_1 . From that point on, the friction coefficient at contact 2 is the limiting factor. To increase the metric further, μ_2 must be increased.

38.5.2 Example 2: Grasped Polygon in the Plane

Part 1: \mathbf{G} and \mathbf{J}

Figure 38.15 shows a planar hand grasping a polygon. Finger 1 (on the right) contains two joints numbered 1 and 2. Finger 2 contains joints 3–7, which are numbered in increasing order moving from the palm distally. The inertial frame has been chosen to lie inside the object, with its x -axis passing through contacts 1 and 2, and collinear with the normal vector of contact 2.

Fig. 38.14 Plot of force closure metric versus friction coefficient on contact 1

Fig. 38.15 Planar hand with 2 fingers and 7 joints grasping a polygonal object

The rotation matrices are given by

$$\mathbf{R}_1 = \begin{pmatrix} -0.8 & -0.6 \\ 0.6 & -0.8 \end{pmatrix}, \quad \mathbf{R}_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \quad (38.86)$$

Assuming **HF** contacts, \mathbf{G} is given as follows

$$\mathbf{G} = \left(\begin{array}{cc|cc} -0.8 & -0.6 & 1 & 0 \\ 0.6 & -0.8 & 0 & 1 \\ l_6 & -l_7 & 0 & -l_8 \end{array} \right). \quad (38.87)$$

Notice that the first two columns of \mathbf{G} correspond to the normal and tangential unit vectors at contact 1. The third and fourth columns correspond to contact 2.

Assuming **HF** contacts and all joints are active (i. e., not locked), \mathbf{J} is

$$\mathbf{J}^T = \left(\begin{array}{cc|cc} 0.8l_1 & 0.6l_1 & \mathbf{0} & \\ -0.6l_2 & 0.8l_2 & & \\ \hline & & -l_1 & 0 \\ & & -l_3 & 0 \\ \mathbf{0} & & -l_3 & l_5 \\ & & -l_3 + l_4 & l_5 \\ & & -l_3 + l_4 & 0 \end{array} \right). \quad (38.88)$$

The first two columns of \mathbf{J}^T are the torques required to produce a unit force in the $\hat{\mathbf{n}}_1$ and $\hat{\mathbf{t}}_1$ directions at contact 1. The horizontal line through the matrix partitions the contributions for the first finger (the upper part) and second finger. Notice that both \mathbf{J}^T and \mathbf{G} are full column rank.

Example 2, Part 2: Grasp Classes

This example clearly illustrates the physical qualities of the various grasp classes without introducing features that can cloud the descriptions.

We now discuss the details of the four grasp classes using the previous planar example. During these discussions it is useful to choose non-dimensional values for the parameters in the grasping system. The lengths were assumed to have the following values (the results are the same, regardless of a particular choice of units, so units are not specified)

$$l_1 = 2.89, \quad l_2 = 0.75, \quad l_3 = 1.97, \quad (38.89)$$

$$l_4 = 0.80, \quad l_5 = 0.80, \quad l_6 = 0.90, \quad (38.90)$$

$$l_7 = 1.20, \quad l_8 = 1.35. \quad (38.91)$$

Redundant. Redundancy exists if $\mathcal{N}(\mathbf{J})$ is non-trivial. Assuming that both contacts are hard contacts and all the joints are active, $\text{rank}(\mathbf{J}) = 4$, so $\mathcal{N}(\mathbf{J})$ is three-dimensional. A basis for $\mathcal{N}(\mathbf{J})$ was obtained using Matlab's `null()` function

$$\mathbf{N}(\mathbf{J}) \approx \left(\begin{array}{ccc} 0 & 0 & 0 \\ 0 & 0 & 0 \\ \hline -0.49 & -0.31 & -0.27 \\ 0.53 & 0.64 & -0.17 \\ 0.49 & -0.50 & -0.02 \\ -0.49 & 0.50 & 0.02 \\ -0.02 & 0.01 & 0.95 \end{array} \right). \quad (38.92)$$

Since the first two rows are zero, $\mathcal{N}(\mathbf{J})$ does not include motions of the first finger (on the right of the palm). To understand this, assume the object is fixed in the plane. Then the first finger cannot maintain sticking contact at contact 1 unless its joints are also fixed.

The three non-zero columns corresponding to finger 2 show that there are 3 basis motions of its joints that allow the finger contact to stick to the object contact. For example, the first column shows that if joint 3 moves roughly as much as joints 4, 5, and 6, but in the opposite direction as joints 4 and 5 and in the same direction as joint 6, while joint 7 is more or less fixed, then contact 2 will be maintained.

Notice that finger 2 contains a parallelogram. Because of this geometry, one can see that the vector $(0\ 0\ 0\ -1\ 1\ -1\ 1)^T$ is an element of $\mathcal{N}(\mathbf{J})$. The velocity interpretation of this vector is that the link of the finger connected to the palm, and the link touching the object remain fixed in space, while the parallelogram moves as a simple four-bar mechanism. Similarly, joint actions in $\mathcal{N}(\mathbf{J})$ do not affect the contact forces, but cause internal hand velocities. Also, notice that since $\mathcal{N}(\mathbf{J}^T) = \mathbf{0}$, the entire space of possible generalized velocities and forces at the contacts can be generated by the joints.

Indeterminate. As noted above, with HF contact models, the system is graspable. However, replacing the HF models with PwoF models removes the tangent force components in the $\hat{\mathbf{i}}_1$ and $\hat{\mathbf{i}}_2$ directions. This effectively removes columns 2 and 4 from \mathbf{G} , which guarantees that the system will be indeterminate. The reduced matrix is denoted by $\mathbf{G}_{(1,3)}$. In this case $\mathcal{N}(\mathbf{G}_{(1,3)}^T)$ is

$$\mathbf{N}(\mathbf{G}_{(1,3)}^T) \approx \begin{pmatrix} 0 \\ -0.83 \\ 0.55 \end{pmatrix}. \quad (38.93)$$

Physically, this basis vector corresponds to moving the object such that the point coincident with the origin of $\{\mathbf{N}\}$ moves directly downward, while the object rotates counter clockwise. Also, if the analogous force and moment were applied to the object, the frictionless contacts could not maintain equilibrium.

Graspable. With two HF contact models in force, $\text{rank}(\mathbf{G}) = 3$, so $\mathcal{N}(\mathbf{G})$ is one-dimensional and the system is graspable. The null space basis vector of the grasp matrix is

$$\mathbf{N}(\mathbf{G}) \approx \begin{pmatrix} 0.57 \\ 0.42 \\ 0.71 \\ 0 \end{pmatrix}. \quad (38.94)$$

The physical interpretation of this basis vector is two opposing forces acting through the two contact points.

Recall that because the contact model is kinematic, there is no consideration of contact friction. However, given the direction of the contact normal relative to the line of the internal force, one can see that if the coefficient of friction is not greater than 0.75, squeezing tightly will cause sliding at contact 1, thus violating the kinematic contact model.

Defective. In a defective grasp, $\mathcal{N}(\mathbf{J}^T) \neq \mathbf{0}$. Given that the original \mathbf{J} is full row rank, the grasp is *not* defective. However, it can be made defective by locking a number of joints and/or changing the hand's configuration so that \mathbf{J} is no longer full rank. For example, locking joints 4, 5, 6, and 7 makes finger 2 a single-link finger with only joint 3 active. In this new grasping system, $\mathbf{J}_{(1,2,3)}^T$ is simply the first three rows of the original \mathbf{J}^T given in (38.88), where the subscript is the list of indices of active joints. The null space basis vector is

$$\mathbf{N}(\mathbf{J}_{(1,2,3)}^T) = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}. \quad (38.95)$$

This grasp is defective, since there is a subspace of contact velocities and forces that cannot be controlled by joint generalized velocities and forces. Since only the last component of $\mathbf{N}(\mathbf{J}_{(1,2,3)}^T)$ is non-zero, it would be impossible for the hand to give the contact point 2 on the object a velocity in the $\hat{\mathbf{i}}_2$ -direction while maintaining the contact. This is also clear from the arrangement of joint 3, contact 2, and the direction of the contact normal. The dual interpretation is that forces in $\mathcal{N}(\mathbf{J}^T)$ are resisted by the structure and the corresponding joint loads is zero, or equivalently that those forces are not controllable by the hand. Notice that if the model of contact 2 were changed to point-without-friction, then $\mathbf{N}(\mathbf{J}_{(1,2,3)}^T) = \mathbf{0}$ and the system would no longer be defective.

38.5.3 Example 3: Hyperstatic Grasps

Part 1: $\tilde{\mathbf{G}}$ and $\tilde{\mathbf{J}}$

Figure 38.16 shows a planar projection of a three-dimensional sphere of radius l grasped by one finger only, with 3 revolute joints, through 3 contacts. The frames $\{\mathbf{C}\}_1$, $\{\mathbf{C}\}_2$ and $\{\mathbf{C}\}_3$ are oriented so that their $\hat{\mathbf{o}}$ -directions point out of the plane of the figure (as indicated by the small filled circle). The axes of the frames $\{\mathbf{N}\}$ and $\{\mathbf{B}\}$ were chosen to be axis-aligned with coincident origins located at the center of the sphere. The \mathbf{z} -axes are pointing out of the page. Observe that since

Fig. 38.16 A sphere grasped by a finger with three revolute joints. The force direction λ_h (dashed line) is a force that belongs to both $\mathcal{N}(\mathbf{G})$ and $\mathcal{N}(\mathbf{J}^T)$ and causes hyperstaticity

the three joint axes of the finger are perpendicular to the (x, y) -plane, the grasp operates in that plane for all time.

Assume that the width of all the links of the robotic hand is zero. Rotation matrices \mathbf{R}_i and vectors $\mathbf{c}_i - \mathbf{p}$ for $i = 1, \dots, 3$, can be computed as in (38.66) and (38.67) considering that $\theta_1 = \pi$, for contact 1, $\theta_2 = \pi/2$ and $\theta_3 = 0$, for contact 2 and 3, respectively. Finally, the complete grasp matrix is

$$\tilde{\mathbf{G}}^T = (\tilde{\mathbf{G}}_1 \quad \tilde{\mathbf{G}}_2 \quad \tilde{\mathbf{G}}_3)^T \in \mathbb{R}^{18 \times 6},$$

where $\tilde{\mathbf{G}}_i$ is as defined in (38.68)

$$\tilde{\mathbf{G}}^T = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & 0 & l & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ \hline 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & l & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ \hline -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & 0 & -l & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

Construction of the complete hand Jacobian $\tilde{\mathbf{J}}_i$ for contact i requires knowledge of the joint axis directions and

the origins of the frames fixed to the links of each finger. Assume that the origins of the Denavit–Hartenberg (DH) frames lie in the plane of the figure. In the current configuration, the quantities of interest for contact 1, expressed directly in $\{\mathbf{N}\}$ are

$$\begin{aligned} \mathbf{c}_1 - \boldsymbol{\xi}_1 &= (0 \quad l \quad 0)^T, \\ \hat{\mathbf{z}}_1 &= (0 \quad 0 \quad 1)^T. \end{aligned}$$

The quantities of interest for contact 2, in $\{\mathbf{N}\}$ are

$$\begin{aligned} \mathbf{c}_2 - \boldsymbol{\xi}_1 &= (l \quad 2l \quad 0)^T, \\ \mathbf{c}_2 - \boldsymbol{\xi}_2 &= (l \quad 0 \quad 0)^T, \\ \hat{\mathbf{z}}_1 &= (0 \quad 0 \quad 1)^T, \\ \hat{\mathbf{z}}_2 &= (0 \quad 0 \quad 1)^T. \end{aligned}$$

The quantities of interest for contact 3, in $\{\mathbf{N}\}$ are

$$\begin{aligned} \mathbf{c}_3 - \boldsymbol{\xi}_1 &= (2l \quad l \quad 0)^T, \\ \mathbf{c}_3 - \boldsymbol{\xi}_2 &= (2l \quad -l \quad 0)^T, \\ \mathbf{c}_3 - \boldsymbol{\xi}_3 &= (0 \quad -l \quad 0)^T, \\ \hat{\mathbf{z}}_1 &= (0 \quad 0 \quad 1)^T, \\ \hat{\mathbf{z}}_2 &= (0 \quad 0 \quad 1)^T, \\ \hat{\mathbf{z}}_3 &= (0 \quad 0 \quad 1)^T. \end{aligned}$$

The complete hand Jacobian $\tilde{\mathbf{J}} \in \mathbb{R}^{18 \times 3}$ (contact velocities are expressed in $\{\mathbf{C}\}_i$) is

$$\tilde{\mathbf{J}} = \begin{pmatrix} -l & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \\ \hline -l & -l & 0 \\ -2l & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 1 & 0 \\ \hline l & -l & -l \\ -2l & -2l & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 1 & 1 \end{pmatrix}.$$

The horizontal dividing lines partition $\tilde{\mathbf{J}}$ into $\tilde{\mathbf{J}}_1$ (on top), $\tilde{\mathbf{J}}_2$, and $\tilde{\mathbf{J}}_3$ (on the bottom). The columns correspond to joints 1 through 3.

Example 3, Part 2: \mathbf{G} and \mathbf{J}

Assume that the 3 contacts in Fig. 38.16 are of type HF. Then the selection matrix \mathbf{H} is given by

$$\mathbf{H} = \begin{pmatrix} \mathbf{I} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} \end{pmatrix}, \quad (38.96)$$

where \mathbf{I} and $\mathbf{0}$ are in $\mathbb{R}^{3 \times 3}$, thus matrices $\mathbf{G}^T \in \mathbb{R}^{9 \times 6}$ and $\mathbf{J} \in \mathbb{R}^{9 \times 3}$ are obtained by removing rows related to rotations from $\tilde{\mathbf{G}}^T$ and $\tilde{\mathbf{J}}$

$$\mathbf{G}^T = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & 0 & l & 0 \\ \hline 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & l & 0 & 0 \\ \hline -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & -l \\ 0 & 0 & 1 & 0 & -l & 0 \end{pmatrix},$$

$$\mathbf{J} = \begin{pmatrix} l & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ \hline l & l & 0 \\ 2l & 0 & 0 \\ 0 & 0 & 0 \\ \hline l & l & l \\ 2l & 2l & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Example 3, Part 3: Grasp Classes

The first column of Table 38.12 reports the dimensions of the main subspaces of \mathbf{J}^T and \mathbf{G} for the sphere grasping example with three hard finger contacts. Only non-trivial null spaces are listed.

The system is defective because there are generalized contact forces belonging to the subspace that are resisted by the structure, which correspond to zero joint

Table 38.12 Dimensions of main subspaces and classification of grasp given in Example 3

Dimension	Class
$\dim \mathcal{N}(\mathbf{J}^T) = 6$	Defective
$\dim \mathcal{N}(\mathbf{G}) = 3$	Graspable
$\dim \mathcal{N}(\mathbf{J}^T) \cap \mathcal{N}(\mathbf{G}) = 1$	Hyperstatic

actions

$$\mathbf{N}(\mathbf{J}^T) = \begin{pmatrix} 0 & 0 & 0 & 0 & -2 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 & -2 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

The first three columns represent generalized forces acting at the three contact points in a direction perpendicular to the plane of the Fig. 38.16. The fourth column corresponds to a contact force applied only along the \hat{t}_1 direction.

System is graspable because the subspace of internal forces is three-dimensional; a possible basis matrix is

$$\mathbf{N}(\mathbf{G}) = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 0 & 0 \\ \hline 1 & 0 & 2 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{pmatrix}.$$

The three force vectors of subspace $\mathbf{N}(\mathbf{G})$ are easily identified from Fig. 38.16. Note that all forces are expressed in local contact frames. The first column vector of $\mathbf{N}(\mathbf{G})$ represents opposed forces at contacts 1 and 2 along the line joining contacts 1 and 2. The second column vector parameterizes opposed forces at contacts 1 and 3 along the line joining contacts 1 and 3. The last vector represents forces along direction λ_h , shown as the (dashed lines) in Fig. 38.16. Note that this direction (in wrench intensity space) corresponds to two upward friction forces at the left and right contacts and one downward with double the magnitude from the center of the top link in the work space.

Finally, the grasp is hyperstatic because

$$\mathbf{N}(\mathbf{G}) \cap \mathbf{N}(\mathbf{J}^T) = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 2 \\ 0 \\ 0 \\ \hline 0 \\ 0 \\ -1 \\ 0 \end{pmatrix} \neq \mathbf{0}.$$

Hyperstatic forces in this subspace, are internal forces that cannot be controlled through the hand joints. In Fig. 38.16 the internal force λ_h that is also in $\mathbf{N}(\mathbf{J}^T)$ is reported.

The grasp in Fig. 38.16 is an example of *power grasp*, style of grasp mentioned earlier that uses many contact points not only on the fingertips but also on the links of fingers and the palm [38.8, 28, 33].

All power grasps are kinematically defective ($\mathcal{N}(\mathbf{J}^T) \neq \mathbf{0}$) and usually are hyperstatic. According to Sect. 38.2.2, rigid-body modeling is not sufficient to capture the overall system behavior, because the generalized contact forces in $\mathcal{N}(\mathbf{G}) \cap \mathcal{N}(\mathbf{J}^T)$ leave the dynamics indeterminate.

Many approaches have been used to overcome rigid-body limitation in hyperstatic grasps such as those proposed in [38.16, 20, 21] where visco-elastic contact models have been used to solve the force indeterminacy. In [38.48], authors found that a sufficient condition for hyperstaticity is $m > q + 6$ where m is the dimension of contact force vector.

38.5.4 Example 4: Duality

Consider a frictionless disc constrained to translate in the plane; (Fig. 38.17). In this problem $n_v = 2$, so the space of applied contact forces and object velocities is

Fig. 38.17 Case of a translating disc in the plane: Relationship between frictionless contacts and possible disc velocities and net contact forces

the plane \mathbb{R}^2 . In the top pair of pictures, a single (fixed) contact point imposes a half space constraint on the instantaneous velocity and limits the force at a frictionless contact to the ray. Both the ray and the (dark gray) half space are defined by the contact normal pointing into the object. Notice that the ray and half space are dual cones. When two contacts are present, the (light gray) force cone becomes the non-negative span of the two contact normals and the velocity cone is its dual. With the addition of the third contact, the grasp has form closure as indicated by the degeneration of the velocity cone to the origin and the expansion of the force cone to become equal to the plane.

It is important to point out that the discussion of the dual cones applies to three-dimensional bodies after replacing the contact normals with the columns of \mathbf{G} .

38.5.5 Example 5: Form Closure

Part 1: Unilateral Constraints

Form closure of a spatial object requires seven unilateral contacts, which is difficult to illustrate. Therefore, the only form closure example analyzed in this chapter is the planar problem shown in Fig. 38.18. In the plane only four unilateral contacts are needed. In this problem, even though the fourth contact is at a vertex of the object, the contact normal is still well-defined. The angle α of the finger is allowed to vary, and it can be shown that form closure exists if α lies in the interval: $1.0518 < \alpha < \frac{\pi}{2}$. Notice that a critical value of α occurs when the lower edge of C_2 contains contact point 3 ($\alpha \approx 1.0518$) and contact point 2 ($\alpha = \frac{\pi}{2}$). Beyond these angles, the cone C_1 and C_2 can no longer see each other.

Choosing the frame for analysis with origin at the fourth contact point, the grasp matrix for this example

Fig. 38.18 Plot of closure metrics versus angle of contact for $1.04 < \alpha < 1.59$

Fig. 38.19 Planar grasp with first-order form closure if $1.052 < \alpha < \frac{\pi}{2}$

is

$$\mathbf{G} = \begin{pmatrix} 0 & 0 & 1 & -\cos(\alpha) \\ 1 & 1 & 0 & -\sin(\alpha) \\ -l & 0 & \frac{7}{4}l & 0 \end{pmatrix}. \quad (38.97)$$

Form closure was tested for a range of angles. The blue curve in Fig. 38.19 is the LP1 metric ($d^* \cdot n_c$ returned by the function `formClosure.m`, available from [38.43]), which indicates that the grasp farthest from losing form closure has $\alpha \approx 1.222$ radians, which is the configuration shown in Fig. 38.18. For comparison purposes, the Ferrari–Canny metric (scaled to have the same maximum as the LP1 metric) is plotted in red. They agree on the angles for which form closure exists, but differ on the optimal α .

Example 5, Part 2: Bilateral Constraints

Let us next consider form closure with a mix of bilateral and unilateral constraints using (38.54). For example, if contact 1 is treated as a bilateral constraint and the remaining are considered to be unilateral, \mathbf{G}_n and \mathbf{B} are

$$\mathbf{B} = \begin{pmatrix} 0 \\ 1 \\ -l \end{pmatrix}, \quad \mathbf{G}_n = \begin{pmatrix} 0 & 1 & -\cos(\alpha) \\ 1 & 0 & -\sin(\alpha) \\ 0 & \frac{7}{4}l & 0 \end{pmatrix}. \quad (38.98)$$

Additional contacts can be converted to bilateral by moving their corresponding columns from \mathbf{G}_n to \mathbf{B} . Figure 38.20 shows five plots of the form closure metric LP1. In the legend, 4 refers to the grasp with all four contacts treated as unilateral, 5 means that contact 1 has been converted to bilateral as defined by the previous equation, 6 means that contacts 1 and 2 have been

Fig. 38.20 First-order form closure metric for Fig. 38.18 with progressively more contacts converted to bilateral

Fig. 38.21 Comparison of the monotonicity properties of the LP1 and Ferrari–Canny form closure metrics

converted to bilateral, etc. The plots show an important property of the LP1 metric; the maximum value is equal to the number of unilateral contacts (bilateral contacts count as two unilateral contacts), which is attained for curves 7 and 8. For this particular problem, these maxima are achieved for all α .

Example 5, Part 3: Monotonicity

If one were to zoom in on curves 4 and 5 near $\alpha = 1.5$, one would see that LP1 is not monotonic as constraints are added. That is, when contact 1 is converted from unilateral (curve 4) to bilateral (curve 5), for some values of α , the LP1 metric is smaller despite the additional constraint. To demonstrate monotonicity, the monotonic Ferrari–Canny metric and the non-monotonic LP1

metric were computed as a function of α for a sequence of grasps. Starting with the original four contacts, five unilateral contacts were added: $\{(0, -1.3l), (-0.5l, 0), (0, 1.75l), (-l, -0.6l), (-0.7l, 0)\}$. Figure 38.21 shows the metrics with 4, 5, 6, 7, 8, and 9 contacts, as indicated by the legend.

The LP1 metric does not increase monotonically as contacts are added for every α . Near $\alpha = 1.2$ adding

the fifth contact reduces the metric slightly. Also, near $\alpha = 1.55$, adding the eighth contact reduces the metric. By contrast, the Ferrari–Canny metric is monotonic, although not strictly monotonic; the plots labeled 6 and 7 are identical for all α and there are other intervals of α where the metric is constant as contacts are added. For example, near $\alpha = 1.35$, the grasps with 5, 6, and 7 contacts all have the same metric value.

38.6 Conclusion and Further Reading

A great deal of understanding of grasping systems can be derived from the simple linear kinematic, dynamic, and contact models presented in this chapter. The most widely used grasp classifications and closure properties can all be derived from these models under the rigid-body assumption. Linearizing these models leads to metrics and tests that can be computed efficiently using computational linear algebra and linear programming techniques. Grasp synthesis tools built on these tests take object and hand models as inputs and return a set of possible grasp configurations as outputs (see for example [38.3]). In-depth discussions of grasp kinematics and grasp classifications can be found in [38.15, 20, 20, 34, 48–52].

One has to wonder what insights have been lost as a result of the simplifying assumptions made in this chapter. For the interested reader, there are a host of papers that analyze grasping systems under more sophisticated assumptions. In general, bodies are curved and compliant [38.17, 28, 35, 53–55] and contact friction models are not quite as simple as the linearized ones so widely adopted. For example, if a contact has to resist a moment about its normal, its effective tangential friction coefficient is reduced [38.46, 56]. In this chapter, the quadratic Coulomb friction cone was approximated by a polyhedral cone. The analysis problems are more difficult when using the quadratic cone, but they are quite tractable [38.47, 57].

In principle, a properly designed grasping system could be controlled to maintain all contacts, but worldly realities can lead to unwanted slipping or twisting. This leads us back to the topic of grasp stability, which is too often equated to grasp closure. However, grasp closure is really equivalent to the existence of equilibrium, which is a necessary, but not sufficient, condition for stability. The common definition of stability outside of the field of robotic grasping requires that when a system is deflected from an equilibrium point, the system returns to this point. From this perspective, and under the assumption of no slipping at the contact points, it is known that all closure grasps are stable, but

the converse is not necessarily true [38.53, 54, 58, 59]. However, stability analysis when contacts slide is still an open question.

Given a stable grasp, another important consideration not discussed in this chapter is that of grasp force distribution problem, i.e., finding *good* actuator torques and contact forces to balance a given external load applied to the object. This problem was studied in the context of walking machines first by McGhee and Orin [38.60] and later by several others [38.61, 62]. Kumar and Waldron applied similar techniques to force distribution problems in grasping [38.63]. Work by Han et al. and Buss et al. solved the force distribution problem with non-linear friction cone constraints by taking advantage of convex optimization techniques [38.47, 57, 64]. In power grasps, this problem of finding a good distribution is difficult, because the space of controllable contact wrenches is severely restricted by the large number of contacts [38.21, 32, 33, 65].

Grasp synthesis largely depends on the structure of the robotic hands that are often very complex systems with many degrees of freedom, sensors and actuators, which are necessary to adapt to many different objects and tasks. An important research area, not discussed in this chapter, is that of designing simplified hands coupling some of the degrees of freedom, reducing the number of effective inputs, and leading to more efficient, simpler and reliable designs [38.23, 66]. A reduction of independent inputs is observed also in human hand movement data, where few variables, defined as postural synergies, explain most of the variance in the configurations of the hand while grasping different objects [38.25, 67]. The reduction of the number of independently controlled inputs in the hand affects grasp properties, and in particular the ability of the hand to dexterously controlling grasp forces and in-hand manipulation as discussed in [38.68–71].

All of the above considerations implicitly assume that a grasp has been achieved, which is no easy task. The bulk of today's research in robotic grasping can be fairly characterized as focused on *grasp acquisition*.

In other words, the problem is to move the hand from a state of no contact with the object to one in which a satisfactory grasp has been achieved. When a robot identifies an object to grasp, its knowledge of the object's pose and geometry are not perfect. Even if they were, the robot's control system could not move the hand perfectly to the desired grasping points. The hand will bump the object accidentally, altering its pose, possibly leading to grasp failure.

Areas of current research cover methods that exploit some detailed aspects of planned or sensed contact interactions that occur before achieving the final grasp and those that try to be robust to pre-grasp contact interactions. In the first category are quasistatic push-grasping, dynamic grasp acquisition, and perception. Push-grasping seeks out contact prior to wrapping the fingers in order to allow the object to settle into a good position against the palm. It has, so far, been applied to objects that can slide stably across a horizontal surface cluttered with object that are not to be grasped [38.72]. Dynamic planning combines a dynamic model of grasping that includes intermittent contact to design optimal controllers and grasping actions

simultaneously [38.73]. The performance of both of the above in real-time implementations could be improved by new grasp perception methods, which estimate the pose of the object relative to the hand [38.74–76].

Impedance controllers are being developed to reduce the negative effects of unexpected contacts between the hand and object as the grasp is being formed [38.77] and between the object and environment during object transport tasks [38.78]. Independent contact regions are surface patches on the object which have the property: if a contact point is stabilized anywhere inside each region, then the grasp will have force closure [38.79, 80]. With this approach, a small amount of jostling will not cause grasp failure. Perhaps caging takes the independent regions idea to the extreme. Here the goal is to find a configuration of the hand that loosely surrounds the object with the additional condition that the object cannot escape without deforming itself or the hand [38.81, 82]. The challenges in caging are in finding a pre-cage configuration and a finger motion plan that impose the least restrictive accuracy requirements on the robots perception and control systems.

39. Cooperative Manipulation

Fabrizio Caccavale, Masaru Uchiyama

This chapter is devoted to cooperative manipulation of a common object by means of two or more robotic arms. The chapter opens with a historical overview of the research on cooperative manipulation, ranging from early 1970s to very recent years. Kinematics and dynamics of robotic arms cooperatively manipulating a tightly grasped rigid object are presented in depth. As for the kinematics and statics, the chosen approach is based on the so-called symmetric formulation; fundamentals of dynamics and reduced-order models for closed kinematic chains are discussed as well. A few special topics, such as the definition of geometrically meaningful cooperative task space variables, the problem of load distribution, and the definition of manipulability ellipsoids, are included to give the reader a complete picture of modeling and evaluation methodologies for cooperative manipulators. Then, the chapter presents the main strategies for controlling both the motion of the cooperative system and the interaction forces between the manipulators and the grasped object; in detail, fundamentals of hybrid force/position control, proportional-derivative (PD)-type force/position control schemes, feedback linearization techniques, and impedance control approaches are given. In the last section further reading on advanced topics related to control of cooperative

robots is suggested; in detail, advanced nonlinear control strategies are briefly discussed (i.e., intelligent control approaches, synchronization control, decentralized control); also, fundamental results on modeling and control of cooperative systems possessing some degree of flexibility are briefly outlined.

It was not long after the emergence of robotics technologies that multi-arm robot systems began to be investigated by robotics researchers. In the early 1970s, research on this topic had already started. This interest was mainly due to typical limitations in applications of single-arm robots. It has been recognized, in fact, that many tasks that are difficult or impossible to execute by a single robot become feasible when two or more manipulators are employed in a cooperative

way. Such tasks include, for instance, carrying heavy or large payloads, the assembly of multiple parts without using special fixtures, and handling of objects that are flexible or possess extra degrees of freedom. Research on this subject has been aimed at solving existing problems and opening up a new stream of applications in flexible manufacturing systems as well as in poorly structured environments (e.g., outer space and undersea).

39.1 Historical Overview

Examples of research work in the early days include that by *Fujii* and *Kurono* [39.1], *Nakano* et al. [39.2], and *Takase* et al. [39.3]. Already in those pieces of work important key issues in the control of multi-arm robots were investigated: master/slave control, force/compliance control, and task-space control. In [39.1] *Fujii* and *Kurono* proposed to adopt a compliance control concept for the coordination of multiple manipulators; they defined a task vector with respect to the object frame and controlled the compliance expressed in the same coordinate frame. An interesting feature of the work by *Fujii* and *Kurono* [39.1] and by *Takase* et al. [39.3] is that force/compliance control was implemented by exploiting back-drivability of the actuators, without using force/torque sensors. The importance of this technique in practical applications, however, was not recognized at that time, and more complex approaches using force/torque sensors lured people in robotics. *Nakano* et al. [39.2,4] proposed a master/slave force control approach for the coordination of two arms carrying an object cooperatively and pointed out the necessity of force control for cooperative multiple robots.

In the 1980s, based on several fundamental theoretical results for single-arm robots, strong research on multi-arm robotic systems was renewed [39.5]. Definition of task vectors with respect to the object to be handled [39.6], dynamics and control of the closed kinematic chain formed by the multi-arm robot and the object [39.7,8], and force control issues, such as hybrid position/force control [39.9–12], were explored. Through this research work, a strong theoretical background for the control of multi-arm robots has been formed, providing the basis for research on more advanced topics from the 1990s to today.

How to parameterize the constraint forces/moments on the object based on the dynamic model of the whole cooperative system has been recognized as a critical issue; in fact, this parametrization leads to the definition of task variables for the control and hence to an answer to one of the most frequently asked questions in the field of multi-arm robotics: how to control simultaneously the trajectory of the object, the mechanical stresses (internal forces/moments) acting on the object, load sharing among the arms, and even the external forces/moments on the object. Force decomposition may be a key to solving these problems and has been studied by *Uchiyama* and *Dauchez* [39.11,12] and *Walker* et al. [39.13] as well as *Bonitz* and *Hsia* [39.14]. In detail, devising a geometrically clear parametrization of the internal forces/moments acting on the object has been recognized as an important

problem, solved in [39.15,16]. Several cooperative control schemes based on the sought parameterizations have been designed, including control of motion and force [39.11,12,17–19] and impedance/compliance control [39.20–22]. Other approaches include adaptive control [39.23,24], kinematic control [39.25], task-space regulation [39.26], joint-space control [39.27,28], and coordinated control [39.29].

Also, the definition of user-oriented task-space variables for coordinated control [39.26,30] and the development of meaningful performance measures [39.31–34] have been fruitfully investigated in 1990s.

Load sharing among the arms is also an interesting issue on which many papers have been published [39.35–40]. Load sharing may be exploited both for optimal load distribution among arms and for robust holding of the object, when the object is held by the arms without being grasped rigidly. In both cases, anyhow, this becomes a problem of optimization and can be solved by either heuristic [39.41] or mathematical methods [39.42].

Other research efforts have been focused on cooperative handling of multibodied or even flexible objects [39.43–45]. Control of multi-flexible-arm robots has been investigated [39.46–48], since the merits of flexible-arm robots can be exploited in cooperative systems [39.49], i.e., lightweight structure, intrinsic compliance and hence safety, etc.

Robust holding of an object in the presence of slippage of end-effectors on the object may be achieved as well, if the slippage is detected correctly [39.50].

A more recent control framework for cooperative systems is so-called synchronization control [39.51,52]; in this class of approaches the control problem is formulated in terms of suitably defined errors accounting for the motion synchronization between the manipulators involved in the cooperative task. As for the nonlinear control of cooperative manipulation systems, efforts have been spent on intelligent control (e.g., [39.53–55]) as well as on the investigation of control strategies in the presence of partial state feedback [39.56]. The problem of controlling underactuated cooperative manipulators is tackled, e.g., in [39.57].

The problem of the implementation of cooperative control strategies on conventional industrial robots has attracted the increasing interest of the research community. In fact, the control units of industrial robots do not present all the features needed to implement nonlinear torque control schemes, while the integration of force/torque sensing in standard industrial robot control units is often cumbersome and tends to be avoided in in-

dustry for many reasons: unreliability, cost, etc. Hence, the rebirth of the early methods, where force sensors were not used (Fujii and Kurono [39.1], Inoue [39.58]), has become attractive for industrial settings. Hybrid position/force control without using force/torque sensors has been successfully implemented [39.59]. Interesting results on the implementation of effective cooperative control strategies for industrial robots are presented, e.g., in [39.60], where a design approach that makes use of tool-based coordinate systems, trajectory generation, and distributed control of multiple robots is presented. Also, a task planning approach for multi-arm industrial robotic work-cells has been recently proposed in [39.30], together with a language for cooperative task programming.

Another interesting aspect, related to the reliability and safety of cooperative manipulation systems, is investigated in [39.61], where the use of nonrigid grippers is considered to avoid large internal forces and, at the same time, to achieve safe manipulation of the object, even in the presence of failures and unpredicted contacts with the external environment.

It is worth mentioning the strict relationship between issues related to grasping of objects by fingers/hands (widely described in Chap. 38) and those related to cooperative manipulation. In fact, in both cases, multiple manipulation structures grasp a commonly manipulated object. In multifingered hands only some motion components are transmitted through the

contact point to the manipulated object (unilateral constraints), while cooperative manipulation via robotic arms is achieved by rigid (or near-rigid) grasp points and interaction takes place by transmitting all the motion components through the grasping points (bilateral constraints). While many common problems between the two fields can be tackled in a conceptually similar way (e.g., kinetostatic modeling, force control), many other are specific of each of the two application fields (e.g., form and force closure for multifingered hands). Interestingly, a common frame for both cooperative and multifingered manipulation has been proposed [39.25]; namely rolling/sliding of the grasp points on the object is taken into account by modeling the contacts via rotational/prismatic joints; then, the desired manipulator/finger joints trajectories are derived from the desired object motion by using numerical inverse kinematics algorithms. In [39.62–64], contributions to modeling and control of cooperative manipulation systems in the presence of different types of manipulators/object contact can be found. Moreover, since cooperative manipulators can be often viewed as closed-chain mechanisms, a strong link with research related to parallel manipulators (Chap. 18) exists, especially from a modeling point of view.

Finally, it is worth mentioning the important issue of cooperative transportation and manipulation of objects via multiple mobile robotic system [39.65, 66], which is currently subject of investigation.

39.2 Kinematics and Statics

Consider a system composed by M manipulators, each equipped with N_i joints ($i = 1, \dots, M$). Let \mathbf{p}_i denote the (3×1) vector of the position of the i -th end-effector coordinate frame, \mathcal{T}_i , with respect to a common base frame, \mathcal{T} ; let \mathbf{R}_i denote the (3×3) matrix which expresses the orientation of \mathcal{T}_i with respect to the base frame \mathcal{T} .

Both \mathbf{p}_i and \mathbf{R}_i can be expressed as a function of the $(N_i \times 1)$ vector of the joints variables of each manipulator \mathbf{q}_i through the direct kinematics equations

$$\begin{cases} \mathbf{p}_i = \mathbf{p}_i(\mathbf{q}_i), \\ \mathbf{R}_i = \mathbf{R}_i(\mathbf{q}_i). \end{cases} \quad (39.1)$$

Of course, the orientation of the end-effector frame may be expressed in terms of a minimal set of angles, i.e., a set of three Euler angles $\boldsymbol{\phi}_i$. In this case, direct kinematics can be expressed in terms of an operational space (pseudo-)vector \mathbf{x}_i as follows

$$\mathbf{x}_i = \mathbf{k}_i(\mathbf{q}_i) = \begin{pmatrix} \mathbf{p}_i(\mathbf{q}_i) \\ \boldsymbol{\phi}_i(\mathbf{q}_i) \end{pmatrix}. \quad (39.2)$$

The linear $\dot{\mathbf{p}}_i$ and angular $\boldsymbol{\omega}_i$ velocity of the i -th end-effector can be collected in the (6×1) generalized velocities vector $\mathbf{v}_i = (\dot{\mathbf{p}}_i^T \boldsymbol{\omega}_i^T)^T$. Then, the differential direct kinematics can be expressed as

$$\mathbf{v}_i = \mathbf{J}_i(\mathbf{q}_i)\dot{\mathbf{q}}_i, \quad (39.3)$$

where the $(6 \times N_i)$ matrix \mathbf{J}_i is the so-called *geometric Jacobian* of the i -th manipulator (Chap. 2). When the velocity is expressed as the derivative of the operational space vector, differential kinematics takes a formally similar form

$$\dot{\mathbf{x}}_i = \frac{\partial \mathbf{k}_i(\mathbf{q}_i)}{\partial \mathbf{q}_i} \dot{\mathbf{q}}_i = \mathbf{J}_{Ai}(\mathbf{q}_i)\dot{\mathbf{q}}_i, \quad (39.4)$$

where the $(6 \times N_i)$ matrix \mathbf{J}_{Ai} is the so-called *analytical Jacobian* of the i -th manipulator (Chap. 2).

Let us consider the (6×1) vector of the generalized forces acting at the i -th end-effector

$$\mathbf{h}_i = \begin{pmatrix} f_i \\ \mathbf{n}_i \end{pmatrix}, \quad (39.5)$$

where \mathbf{f}_i and \mathbf{n}_i denote the force and moment, respectively. By invoking the principle of virtual work, a relation dual to (39.3) can be derived

$$\boldsymbol{\tau}_i = \mathbf{J}_i^T(\mathbf{q}_i) \mathbf{h}_i, \quad (39.6)$$

where $\boldsymbol{\tau}_i$ is the $(N_i \times 1)$ vector of the forces/torques acting at the joints of the i -th manipulator.

For the sake of simplicity, consider a system of two cooperative robots (Fig. 39.1) manipulating a common object. Let C be a fixed point of the object (e.g., the center of mass of the object), whose position in the base frame is given by the vector \mathbf{p}_C ; moreover, let \mathcal{T}_C be a coordinate frame attached to object with origin in C . The *virtual stick* [39.11, 12] is defined as the vector \mathbf{r}_i ($i = 1, 2$) which determines the position of \mathcal{T}_C with respect to \mathcal{T}_i ($i = 1, 2$); it is assumed that \mathbf{r}_i behaves as a rigid stick fixed to the i -th end-effector. Hence, each virtual stick, expressed in the frame \mathcal{T}_i (or \mathcal{T}_C), is a constant vector if the commonly grasped object is rigid and tightly grasped by each manipulator. In this case, the direct kinematics of each manipulator can be expressed in terms of a virtual end-effector frame $\mathcal{T}_{S,i} = \mathcal{T}_C$, having the same orientation of \mathcal{T}_C and origin located in $\mathbf{p}_{S,i} = \mathbf{p}_i + \mathbf{r}_i = \mathbf{p}_C$. Hence, the position and orientation at the tip of each virtual stick are given by ($i = 1, 2$)

$$\mathbf{p}_{S,i} = \mathbf{p}_C, \quad \mathbf{R}_{S,i} = \mathbf{R}_C.$$

The set of Euler angles corresponding to $\mathbf{R}_{S,i}$ will be denoted by the (3×1) vector $\boldsymbol{\phi}_{S,i}$. Hereafter, it is assumed that the object grasped by the two manipulators can be considered rigid (or nearly rigid) and tightly (or nearly tightly) attached to each end-effector. Hence, the displacements between the above defined frames can be considered null or negligible. Otherwise, if the manipulated object is subject to deformation (e.g., in the case

of a flexible object) and/or the grasp is not tight (e.g., in the case of compliant grippers) the above defined coordinate frames, will be subject to nonnegligible displacements with respect to each other.

Let $\mathbf{h}_{S,i}$ denote the vector of generalized forces acting at the tip of the i -th virtual stick; it can be easily verified that the following equation holds

$$\mathbf{h}_{S,i} = \begin{pmatrix} \mathbf{I}_3 & \mathbf{O}_3 \\ -\mathbf{S}(\mathbf{r}_i) & \mathbf{I}_3 \end{pmatrix} \mathbf{h}_i = \mathbf{W}_i \mathbf{h}_i, \quad (39.7)$$

where \mathbf{O}_l and \mathbf{I}_l denote, respectively, the null matrix and the identity matrix of $(l \times l)$ dimensions, and $\mathbf{S}(\mathbf{r}_i)$ is the (3×3) skew-symmetric matrix operator performing the cross product. It is worth noticing that \mathbf{W}_i is always full rank.

By invoking the virtual works principle, a relation dual to (39.7) can easily be derived

$$\mathbf{v}_i = \begin{pmatrix} \mathbf{I}_3 & \mathbf{S}(\mathbf{r}_i) \\ \mathbf{O}_3 & \mathbf{I}_3 \end{pmatrix} \mathbf{v}_{S,i} = \mathbf{W}_i^T \mathbf{v}_{S,i}, \quad (39.8)$$

where $\mathbf{v}_{S,i}$ is the generalized velocity vector of the virtual stick endpoint. When $\mathbf{r}_i = \mathbf{0}$, it is $\mathbf{W}_i = \mathbf{I}_6$; in other words, if the end-effector kinematics of each manipulator is referred to the corresponding virtual stick (or the object reduces to point), the forces and velocities at the two end-effectors coincide with their counterparts referred at the virtual sticks.

39.2.1 Symmetric Formulation

The kinetostatic formulation proposed by Uchiyama and Dauchez [39.12], i.e., the so-called *symmetric formulation*, is based on kinematic and static relationships between generalized forces/velocities acting at the object and their counterparts acting at the manipulators end-effectors (or at the virtual sticks endpoints).

Let us define first the *external forces* as the (6×1) vector of generalized forces given by

$$\mathbf{h}_E = \mathbf{h}_{S,1} + \mathbf{h}_{S,2} = \mathbf{W}_S \mathbf{h}_S, \quad (39.9)$$

with $\mathbf{W}_S = (\mathbf{I}_6 \ \mathbf{I}_6)$ and $\mathbf{h}_S = (\mathbf{h}_{S,1}^T \ \mathbf{h}_{S,2}^T)^T$; in other words, \mathbf{h}_E represents the vector of generalized forces causing the object's motion. From (39.7) and (39.9) it follows that \mathbf{h}_E can be expressed in terms of end-effector forces as well

$$\mathbf{h}_E = \mathbf{W}_1 \mathbf{h}_1 + \mathbf{W}_2 \mathbf{h}_2 = \mathbf{W} \mathbf{h}, \quad (39.10)$$

with $\mathbf{W} = (\mathbf{W}_1 \ \mathbf{W}_2)$ and $\mathbf{h} = (\mathbf{h}_1^T \ \mathbf{h}_2^T)^T$. It can be recognized that \mathbf{W}_S (\mathbf{W}) is a (6×12) matrix, having a six-dimensional (6-D) range space and a six-dimensional

Fig. 39.1 Grasp geometry for a two-manipulator cooperative system manipulating a common object

null space, describing the geometry of the grasp, and thus is usually termed the *grasp matrix*.

The inverse solution to (39.9) yields

$$\mathbf{h}_S = \mathbf{W}_S^\dagger \mathbf{h}_E + \mathbf{V}_S \mathbf{h}_I = \mathbf{U}_S \mathbf{h}_O, \quad (39.11)$$

where \mathbf{W}_S^\dagger denotes the Moore–Penrose pseudoinverse of \mathbf{W}_S

$$\mathbf{W}_S^\dagger = \frac{1}{2} \begin{pmatrix} \mathbf{I}_6 \\ \mathbf{I}_6 \end{pmatrix}. \quad (39.12)$$

\mathbf{V}_S is a matrix whose columns are a basis of the null space of \mathbf{W}_S , e.g.,

$$\mathbf{V}_S = \begin{pmatrix} -\mathbf{I}_6 \\ \mathbf{I}_6 \end{pmatrix}, \quad (39.13)$$

$\mathbf{h}_O = (\mathbf{h}_E^\top \mathbf{h}_I^\top)^\top$, and

$$\mathbf{U}_S = (\mathbf{W}_S^\dagger \mathbf{V}_S). \quad (39.14)$$

The second term on the right-hand side of (39.11), i. e., $\mathbf{V}_S \mathbf{h}_I$, represents a vector of generalized forces, referred at the tip of the virtual sticks, which lies in the null space of \mathbf{W}_S ; thus, such forces do not contribute to external forces. Hence, the (6×1) vector \mathbf{h}_I is a generalized force which does not contribute to the object's motion. Therefore, it represents internal loading of the object (i. e., mechanical stresses) and is termed the *internal forces* vector [39.12]. A similar argument can be used for equation (39.10), whose inverse solution is

$$\mathbf{h} = \mathbf{W}^\dagger \mathbf{h}_E + \mathbf{V} \mathbf{h}_I = \mathbf{U} \mathbf{h}_O, \quad (39.15)$$

where

$$\mathbf{U} = (\mathbf{W}^\dagger \mathbf{V}). \quad (39.16)$$

In [39.13] it has been shown that the first term on the right-hand side of (39.15) represents only contributions to external forces if the pseudoinverse of the grasp matrix is properly defined, i. e.,

$$\mathbf{W}^\dagger = \begin{pmatrix} \frac{1}{2} \mathbf{I}_3 & \mathbf{O}_3 \\ \frac{1}{2} \mathbf{S}(\mathbf{r}_1) & \frac{1}{2} \mathbf{I}_3 \\ \frac{1}{2} \mathbf{I}_3 & \mathbf{O}_3 \\ \frac{1}{2} \mathbf{S}(\mathbf{r}_2) & \frac{1}{2} \mathbf{I}_3 \end{pmatrix}. \quad (39.17)$$

As \mathbf{V}_S in (39.11), the columns of \mathbf{V} span the null space of \mathbf{W} , and can be chosen as [39.31]

$$\mathbf{V} = \begin{pmatrix} -\mathbf{I}_3 & \mathbf{O}_3 \\ -\mathbf{S}(\mathbf{r}_1) & -\mathbf{I}_3 \\ \mathbf{I}_3 & \mathbf{O}_3 \\ \mathbf{S}(\mathbf{r}_2) & \mathbf{I}_3 \end{pmatrix}. \quad (39.18)$$

A different parametrization of the inverse solutions to (39.9) and (39.10) can be expressed, respectively, as

$$\mathbf{h}_S = \mathbf{W}_S^\dagger \mathbf{h}_E + (\mathbf{I}_{12} - \mathbf{W}_S^\dagger \mathbf{W}_S) \mathbf{h}^* \quad (39.19)$$

and

$$\mathbf{h} = \mathbf{W}^\dagger \mathbf{h}_E + (\mathbf{I}_{12} - \mathbf{W}^\dagger \mathbf{W}) \mathbf{h}^*, \quad (39.20)$$

where \mathbf{h}^* (\mathbf{h}^*) is an arbitrary (12×1) vector of generalized forces acting at the tip of the i -th virtual stick (i -th end-effector) projected onto the null space of \mathbf{W}_S (\mathbf{W}) via $\mathbf{I}_{12} - \mathbf{W}_S^\dagger \mathbf{W}_S$ ($\mathbf{I}_{12} - \mathbf{W}^\dagger \mathbf{W}$).

By exploiting the principle of virtual work, the mappings between generalized velocities, dual to those derived above, can be established. In detail, the mapping dual to (39.11) is

$$\mathbf{v}_O = \mathbf{U}_S^\top \mathbf{v}_S, \quad (39.21)$$

where $\mathbf{v}_S = (\mathbf{v}_{S,1}^\top \mathbf{v}_{S,2}^\top)^\top$, $\mathbf{v}_O = (\mathbf{v}_E^\top \mathbf{v}_I^\top)^\top$. The vector \mathbf{v}_E can be interpreted as the absolute velocity of the object, while \mathbf{v}_I represents the relative velocity between the two coordinate frames $\mathcal{T}_{S,1}$ and $\mathcal{T}_{S,2}$ attached to the tips of the virtual sticks [39.12]; this vector is null when the manipulated object is rigid and rigidly grasped. In a similar way, from (39.15), the following mapping can be devised

$$\mathbf{v}_O = \mathbf{U}^\top \mathbf{v}, \quad (39.22)$$

where $\mathbf{v} = (\mathbf{v}_1^\top \mathbf{v}_2^\top)^\top$.

Moreover, a set of position and orientation variables corresponding to \mathbf{v}_E and \mathbf{v}_I can be defined as follows [39.12, 25]

$$\mathbf{p}_E = \frac{1}{2} (\mathbf{p}_{S,1} + \mathbf{p}_{S,2}), \quad \mathbf{p}_I = \mathbf{p}_{S,2} - \mathbf{p}_{S,1}, \quad (39.23)$$

$$\mathbf{R}_E = \mathbf{R}_1 \mathbf{R}_1^1 (\mathbf{k}_{21}^1, \vartheta_{21}/2), \quad \mathbf{R}_I^1 = \mathbf{R}_2^1, \quad (39.24)$$

where $\mathbf{R}_2^1 = \mathbf{R}_1^\top \mathbf{R}_2$ is the matrix expressing the orientation of \mathcal{T}_2 with respect to the axes of \mathcal{T}_1 , while \mathbf{k}_{21}^1 and ϑ_{21} are, respectively, the equivalent unit vector (expressed with respect to \mathcal{T}_1) and rotation angle that determine the mutual orientation expressed by \mathbf{R}_2^1 . Hence, \mathbf{R}_E expresses a rotation about \mathbf{k}_{21}^1 by an angle which is half the angle needed to align \mathcal{T}_2 with \mathcal{T}_1 .

In turn, if the orientation variables are expressed in terms of Euler angles, a set of operational space variables can be defined as

$$\mathbf{x}_E = \begin{pmatrix} p_E \\ \phi_E \end{pmatrix}, \quad \mathbf{x}_I = \begin{pmatrix} p_I \\ \phi_I \end{pmatrix}, \quad (39.25)$$

where

$$\phi_E = \frac{1}{2}(\phi_{S,1} + \phi_{S,2}), \quad \phi_I = \phi_{S,2} - \phi_{S,1}. \quad (39.26)$$

It must be remarked, however, that the definitions in (39.26) keep a clear geometric meaning only if the orientation displacements between the virtual stick frames are small. In this case, as shown in [39.11, 12], the corresponding operational space velocities, $\dot{\mathbf{x}}_E$ and $\dot{\mathbf{x}}_I$, correspond to \mathbf{v}_E and \mathbf{v}_I , respectively, with good approximation. Otherwise, if the orientation displacements become large, the variables defined in (39.26) do not represent any meaningful quantities, and other orientation representations have to be adopted, e.g., the unit quaternion (see Chap. 2 on kinematics for a general introduction to quaternions and Sect. 39.3 for an application to cooperative robots kinematics).

Finally, by using (39.15) and (39.22), together with equations (39.3) and (39.6), the kinetostatic mappings between the force/velocities at the object and their counterparts in the joint space of the manipulators can be given

$$\boldsymbol{\tau} = \mathbf{J}_O^T \mathbf{h}_O, \quad (39.27)$$

$$\mathbf{v}_O = \mathbf{J}_O \dot{\mathbf{q}}, \quad (39.28)$$

where $\boldsymbol{\tau} = (\tau_1^T \tau_2^T)^T$, $\mathbf{q} = (q_1^T q_2^T)^T$, and

$$\mathbf{J}_O = \mathbf{U}^T \mathbf{J}, \quad \mathbf{J} = \begin{pmatrix} \mathbf{J}_1 & \mathbf{O}_6 \\ \mathbf{O}_6 & \mathbf{J}_2 \end{pmatrix}. \quad (39.29)$$

Formally similar mappings can be established in terms of operational space velocities $\dot{\mathbf{x}}_E$ and $\dot{\mathbf{x}}_I$ [39.11, 12] and the corresponding operational space forces/moments.

39.2.2 Multifingered Manipulation

Hereafter some connections between the field of multi-arm cooperative manipulation, described in this chapter, and multifingered manipulation, described in Chap. 38, are briefly outlined, focusing on the kinetostatics of the two classes of manipulation systems.

Both in the case of multi-arm cooperative systems and of multifingered manipulation, two or more manipulation structures grasp a commonly manipulated object.

Cooperative manipulation via multiple robotic arms is achieved by rigidly grasping the object (e.g., via rigid

fixtures), and thus interaction takes place by exchanging both forces and moments at the grasp points. In other words, all the translational and rotational motion components are transmitted through the grasp points.

On the other side, when a multifingered hand manipulates an object, only some components of the motion are transmitted through the contact points. This is effectively modeled via properly defined constraint matrices, whose expression depends on the type of contact. In other words, constraint matrices act as filters selecting the components of the motion transmitted through each contact. In fact, as shown in Chap. 38, it is convenient to think of the object–finger contact point as twofold: a point on the tip of the finger and a point on the object. Hence, two generalized velocity vectors are defined for the i -th contact point (both expressed with respect to frame \mathcal{T}_i): the velocity of the contact point on the hand, $\mathbf{v}_{h,i}^i$, and the velocity of the contact point on the object $\mathbf{v}_{o,i}^i$. The corresponding dual generalized force vectors are $\mathbf{h}_{h,i}^i$ and $\mathbf{h}_{o,i}^i$, respectively. A contact model is then defined via the $(m_i \times 6)$ constraint matrix \mathbf{H}_i , selecting m_i velocity components transmitted through the contact ($\mathbf{v}_{t,i}^i$), i. e.,

$$\mathbf{v}_{t,i}^i = \mathbf{H}_i \mathbf{v}_{h,i}^i = \mathbf{H}_i \mathbf{v}_{o,i}^i. \quad (39.30)$$

The relation dual to (39.30) is

$$\mathbf{H}_i^T \mathbf{h}_{t,i}^i = \mathbf{h}_{h,i}^i = \mathbf{h}_{o,i}^i, \quad (39.31)$$

where $\mathbf{h}_{t,i}^i$ is the vector of the transmitted generalized forces. Hence, (39.10) can be rewritten as

$$\mathbf{h}_E = \mathbf{W}_1 \bar{\mathbf{R}}_1 \mathbf{H}_1^T \mathbf{h}_{t,1}^1 + \mathbf{W}_2 \bar{\mathbf{R}}_2 \mathbf{H}_2^T \mathbf{h}_{t,2}^2, \quad (39.32)$$

where $\bar{\mathbf{R}}_i = \text{diag}\{\mathbf{R}_i, \mathbf{R}_i\}$. Hence, a conceptually similar kinetostatic analysis can be developed, leading to the concept of external and internal forces (and related kinematic quantities) as well.

However, it must be remarked that, while in the case of cooperative manipulators, tightly grasping the object, internal stresses are usually undesirable effects (unless controlled squeezing of a deformable object has to be achieved), in multifingered hands suitably controlled internal forces are useful to guarantee a firm grasp even in the presence of external loading applied to the object (see the problem of form and force closure discussed in Chap. 38).

39.3 Cooperative Task Space

The symmetric formulation reviewed in Sect. 39.2.1 defines the fundamental variables and the primary relationships needed to describe the kinematics and the statics of the cooperative manipulators. However, the symmetric formulation was not originally conceived for task and motion planning of cooperative robotic systems, since this formulation effectively describes a cooperative system in terms of forces and velocities at the virtual sticks, while the user is expected to plan the task in terms of geometrically meaningful variables describing the position and the orientation of a set of relevant coordinate frames. Thus, starting from equations (39.23) and (39.24), further research efforts have been devoted to define alternative kinematic formulations, explicitly aimed at planning the coordinated motion of general multi-arm systems. A notable example of such alternative formulations is the task-oriented formulation for the definition of the *cooperative task space* originally proposed in [39.25, 26]. By starting from (39.23) and (39.24), this formulation defines directly the task variables in terms of the *absolute* and *relative* motion of the cooperative system, which can be directly computed from the position/orientation of the end-effector coordinate frames.

Let us define as *absolute coordinate frame*, \mathcal{T}_a , the frame whose position in the base frame is given by the position vector \mathbf{p}_a (*absolute position*)

$$\mathbf{p}_a = \frac{1}{2}(\mathbf{p}_1 + \mathbf{p}_2). \quad (39.33)$$

The orientation of \mathcal{T}_a with respect to the base frame (*absolute orientation*) is defined by means of the rotation matrix \mathbf{R}_a

$$\mathbf{R}_a = \mathbf{R}_1 \mathbf{R}_1^1(k_{21}^1, \vartheta_{21}/2). \quad (39.34)$$

Of course, the sole absolute variables cannot uniquely specify the cooperative motion, since 12 variables are required, e.g., for a two-arm system. Hence, in order to devise a complete description of the system's configuration, the position/orientation of each manipulator relative to the other manipulators in the system must be considered. In detail, for a two-arm system, the *relative position* between the manipulators is defined as

$$\mathbf{p}_r = \mathbf{p}_2 - \mathbf{p}_1, \quad (39.35)$$

while the *relative orientation* between the two end-effector frames is expressed via the following rotation matrix

$$\mathbf{R}_r^1 = \mathbf{R}_1^T \mathbf{R}_2 = \mathbf{R}_2^1. \quad (39.36)$$

The variables \mathbf{p}_a , \mathbf{R}_a , \mathbf{p}_r , and \mathbf{R}_r^1 define the *cooperative task space*. Remarkably, \mathbf{R}_a and \mathbf{R}_r^1 coincide with \mathbf{R}_E and \mathbf{R}_I^1 , respectively.

It is worth pointing out a useful feature of the above defined cooperative task space formulation. In fact, it can be recognized that definitions (39.33)–(39.36) are not based on any special assumption on the nature of the manipulated object and/or the grasp. In other words, the cooperative task space variables can be effectively used to describe cooperative systems manipulating non-rigid objects and/or characterized by a non-rigid grasp. Also, the same task-space variables can be used to describe a pure motion coordination task, i.e., when the arms are required to perform a coordinated motion without physically interacting via a commonly manipulated object. When the manipulators hold a rigid object (or a deformable object for which deformations are not commanded), then relative position and orientation are to be kept constant. Otherwise, if a relative motion between the end-effectors is allowed, then \mathbf{p}_r^1 and \mathbf{R}_r^1 may vary according to the actual relative motion.

As shown in [39.25, 26], absolute

$$\dot{\mathbf{p}}_a = \frac{1}{2}(\dot{\mathbf{p}}_1 + \dot{\mathbf{p}}_2), \quad \boldsymbol{\omega}_a = \frac{1}{2}(\boldsymbol{\omega}_1 + \boldsymbol{\omega}_2), \quad (39.37)$$

and relative

$$\dot{\mathbf{p}}_r = (\dot{\mathbf{p}}_2 - \dot{\mathbf{p}}_1), \quad \boldsymbol{\omega}_r = \boldsymbol{\omega}_2 - \boldsymbol{\omega}_1, \quad (39.38)$$

linear and angular velocities can be readily derived, as well as their dual variables (i.e., absolute/relative forces and moments)

$$\mathbf{f}_a = \mathbf{f}_1 + \mathbf{f}_2, \quad \mathbf{n}_a = \mathbf{n}_1 + \mathbf{n}_2, \quad (39.39)$$

$$\mathbf{f}_r = \frac{1}{2}(\mathbf{f}_2 - \mathbf{f}_1), \quad \mathbf{n}_r = \frac{1}{2}(\mathbf{n}_2 - \mathbf{n}_1). \quad (39.40)$$

Kinetostatic mappings, analogous to those derived in the previous section, can be established between linear/angular velocities (force/moments) and their counterparts defined at the end-effectors (or joints) level of each manipulator [39.25, 26].

Remarkably, the variables defined by the symmetric formulation and those used in the task-oriented formulation are related via simple mappings. In fact, forces (angular velocities, orientation variables) always coincide in the two formulations, while moments (linear velocities, position variables) coincide only when the object reduces to a point, or when the kinematics of each manipulator is referred to the tip of the corresponding virtual stick.

As shown in the following example, in the case of planar cooperative systems, the definition of the cooperative task-space variables is straightforward.

Example 39.1 (Cooperative Task-Space Variables for a Planar Two-Arm System)

For a planar two-arm system the i -th end-effector coordinates can be defined via the (3×1) vector

$$\mathbf{x}_i = \begin{pmatrix} \mathbf{p}_i \\ \varphi_i \end{pmatrix}, \quad i = 1, 2,$$

where \mathbf{p}_i is the (2×1) vector of the i -th end-effector position in the plane and φ_i is the angle describing its orientation (i. e., the rotation of the end-effector frame about an axis orthogonal to the plane). Hence, the task-space variables can be readily defined as

$$\mathbf{x}_a = \frac{1}{2}(\mathbf{x}_1 + \mathbf{x}_2), \quad (39.41)$$

$$\mathbf{x}_r = \mathbf{x}_2 - \mathbf{x}_1, \quad (39.42)$$

since the orientation of each end-effector is simply represented by an angle.

In the spatial case, the definition of the orientation variables in terms of Euler angles, as in (39.34) and (39.36), is somewhat critical; in fact, since \mathcal{T}_1 and \mathcal{T}_2 do not coincide in general, orientation displacements are

likely to be large and definitions analogous to (39.26) are not correct. Hence, geometrically meaningful orientation representations have to be adopted, e.g., the unit quaternion (Chap. 2). In detail, by following the approach in [39.26], the orientation variables can be defined as follows. Let

$$\mathcal{Q}_{k>}^1 = \{\eta_k, \epsilon_k^1\} = \left\{ \cos \frac{\vartheta_{21}}{4}, \mathbf{k}_{21}^1 \sin \frac{\vartheta_{21}}{4} \right\} \quad (39.43)$$

denote the unit quaternion extracted from $\mathbf{R}^1(\mathbf{k}_{21}^1, \vartheta_{21}/2)$; let, also, $\mathcal{Q}_1 = \{\eta_1, \epsilon_1\}$ and $\mathcal{Q}_2 = \{\eta_2, \epsilon_2\}$ denote the unit quaternions extracted from \mathbf{R}_1 and \mathbf{R}_2 , respectively. Then, the absolute orientation can be expressed in terms of quaternion product as follows

$$\mathcal{Q}_a = \{\eta_a, \epsilon_a\} = \mathcal{Q}_1 * \mathcal{Q}_k^1, \quad (39.44)$$

while the relative orientation can be expressed as the quaternion product

$$\mathcal{Q}_r^1 = \{\eta_r, \epsilon_r^1\} = \mathcal{Q}_1^{-1} * \mathcal{Q}_2, \quad (39.45)$$

where $\mathcal{Q}_1^{-1} = \{\eta_1, -\epsilon_1\}$ (i. e., the conjugate of \mathcal{Q}_1) represents the unit quaternion extracted from \mathbf{R}_1^T .

Finally, it is worth mentioning that a more general cooperative task-space formulation is developed for different classes of multi-arm robotic systems in [39.30].

39.4 Dynamics and Load Distribution

The equations of motion of the i -th manipulator in a cooperative manipulation system are given by

$$\mathbf{M}_i(\mathbf{q}_i) \ddot{\mathbf{q}}_i + \mathbf{c}_i(\mathbf{q}_i, \dot{\mathbf{q}}_i) = \boldsymbol{\tau}_i - \mathbf{J}_i^T(\mathbf{q}_i) \mathbf{h}_i, \quad (39.46)$$

where $\mathbf{M}_i(\mathbf{q}_i)$ is the symmetric positive-definite inertia matrix and $\mathbf{c}_i(\mathbf{q}_i, \dot{\mathbf{q}}_i)$ is the vector of the forces/torques due to the centrifugal, Coriolis, gravity, and friction effects. The model can be expressed in compact form as

$$\mathbf{M}(\mathbf{q}) \ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) = \boldsymbol{\tau} - \mathbf{J}^T(\mathbf{q}) \mathbf{h}, \quad (39.47)$$

where the matrices are block-diagonal (e.g., $\mathbf{M} = \text{blockdiag}\{\mathbf{M}_1, \mathbf{M}_2\}$) and the vectors are stacked (e.g., $\mathbf{q} = (\mathbf{q}_1^T \mathbf{q}_2^T)^T$).

The object's motion is described by the classical Newton–Euler equations of rigid body

$$\mathbf{M}_E(\mathbf{R}_E) \dot{\mathbf{v}}_E + \mathbf{c}_E(\mathbf{R}_E, \boldsymbol{\omega}_E) \mathbf{v}_E = \mathbf{h}_E = \mathbf{W} \mathbf{h}, \quad (39.48)$$

where \mathbf{M}_E is the inertia matrix of the object and \mathbf{c}_E collects the nonlinear components of the inertial

forces/moments (i. e., gravity, centrifugal and Coriolis forces/moments).

The above equations must be completed by imposing the closed-chain constraints arising from the kinematic coupling between the two manipulators through the commonly manipulated rigid object. The constraints can be expressed by imposing a null internal velocity vector in the mapping (39.21)

$$\mathbf{v}_I = \mathbf{V}_S^T \mathbf{v}_S = \mathbf{v}_{S,1} - \mathbf{v}_{S,2} = \mathbf{0}, \quad (39.49)$$

which can be expressed, by using (39.8) and (39.22), in terms of end-effector velocities (where the notation \mathbf{W}_i^{-T} stands for $(\mathbf{W}_i^T)^{-1}$)

$$\mathbf{V}^T \mathbf{v} = \mathbf{W}_1^{-T} \mathbf{v}_1 - \mathbf{W}_2^{-T} \mathbf{v}_2 = \mathbf{0}, \quad (39.50)$$

and, finally, in terms of joint velocities

$$\mathbf{V}^T \mathbf{J}(\mathbf{q}) \dot{\mathbf{q}} = \mathbf{W}_1^{-T} \mathbf{J}_1(\mathbf{q}_1) \dot{\mathbf{q}}_1 - \mathbf{W}_2^{-T} \mathbf{J}_2(\mathbf{q}_2) \dot{\mathbf{q}}_2 = \mathbf{0}. \quad (39.51)$$

Equations (39.47), (39.48), and (39.51) represent a constrained dynamical model of the cooperative system in the joint space; $N_1 + N_2$ generalized coordinates (i. e., \mathbf{q}_1 and \mathbf{q}_2) are related to each other by the six algebraic closed-chain constraints (39.51). This implies that the total number of degrees of freedom is $N_1 + N_2 - 6$ and the model has the form of a set of differential-algebraic equations.

39.4.1 Reduced-Order Models

The above derived dynamic model incorporates a set of closed-chain constraints, which reduces the number of independent generalized coordinates to $N_1 + N_2 - 6$. Hence, it is expected that, by eliminating six equations via the constraints (39.51), a reduced-order model can be obtained. Early work on reduced-order modeling of closed chains can be, e.g., found in [39.67]. Later, in [39.68, 69], this problem has been tackled by first deriving, from (39.47), (39.48), and (39.51), a joint space model of the whole closed chain in the form

$$\mathbf{M}_C(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}_C(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{D}_C(\mathbf{q})\boldsymbol{\tau}, \quad (39.52)$$

where \mathbf{M}_C , \mathbf{D}_C , and \mathbf{c}_C depend on the dynamics of the manipulators and the object, as well as on the geometry of the grasp. The above model can be integrated, once the joint torques vector $\boldsymbol{\tau}$ is specified over an assigned time interval, to solve for the joint variables \mathbf{q} (*forward dynamics*). However, the model cannot be used to find $\boldsymbol{\tau}$ from assigned \mathbf{q} , $\dot{\mathbf{q}}$, and $\ddot{\mathbf{q}}$ (*inverse dynamics*), since the $((N_1 + N_2) \times (N_1 + N_2))$ matrix \mathbf{D}_C is not full rank [39.69], and thus the inverse dynamics problem turns out to be underspecified.

In order to find a reduced-order model, composed by $N_1 + N_2 - 6$ equations, a $((N_1 + N_2 - 6) \times 1)$ pseudovelocity vector has to be considered

$$\mathbf{v} = \mathbf{B}(\mathbf{q})\dot{\mathbf{q}}, \quad (39.53)$$

where the $((N_1 + N_2 - 6) \times (N_1 + N_2))$ matrix $\mathbf{B}(\mathbf{q})$ is selected so that $(\mathbf{A}^T(\mathbf{q})\mathbf{B}^T(\mathbf{q}))^T$ is nonsingular and

$$\mathbf{A}(\mathbf{q}) = \mathbf{W}_2^T \mathbf{V}^T(\mathbf{q}).$$

Then, the reduced-order model can be written in terms of the variables \mathbf{q} , \mathbf{v} , and $\dot{\mathbf{v}}$ as

$$\boldsymbol{\Sigma}^T(\mathbf{q})\mathbf{M}_C(\mathbf{q})\boldsymbol{\Sigma}(\mathbf{q})\dot{\mathbf{v}} + \boldsymbol{\Sigma}^T(\mathbf{q})\mathbf{c}_R(\mathbf{q}, \mathbf{v}) = \boldsymbol{\Sigma}^T(\mathbf{q})\boldsymbol{\tau}, \quad (39.54)$$

where $\boldsymbol{\Sigma}$ is an $((N_1 + N_2) \times (N_1 + N_2 - 6))$ matrix such that

$$\begin{pmatrix} \mathbf{A} \\ \mathbf{B} \end{pmatrix}^{-1} = (\boldsymbol{\Pi} \boldsymbol{\Sigma}),$$

and \mathbf{c}_R depends on \mathbf{c}_C , $\boldsymbol{\Sigma}$, and $\boldsymbol{\Pi}$ [39.69]. The reduced-order model can be used for computing the forward dynamics; in this case, however, the problem of expressing a reduced set of *pseudocoordinates* related to \mathbf{v} in the numerical integration has to be considered. Since $\boldsymbol{\Sigma}^T$ is nonsquare, the inverse dynamics problem still admits infinitely many solutions in terms of $\boldsymbol{\tau}$. However, this does not prevent the application model (39.54) to cooperative manipulators control (e.g., the decoupled control architecture proposed in [39.68, 69]).

39.4.2 Load Distribution

The problem of load sharing in multi-arm robotic systems is that of distributing the load among the arms composing the system (e.g., a strong arm may share the load more than a weak one). This is possible because a multi-arm system has redundant actuators; in fact, if a robotic arm is equipped with the number of actuators strictly needed for supporting the load, no optimization of load distribution is possible. In this section, this problem is presented according to the results in [39.36–42].

We can introduce a load-sharing matrix in the framework adopted for presenting the kinematics of the cooperative manipulators. By replacing the Moore–Penrose inverse in equation (39.11) with a suitably defined generalized inverse, \mathbf{W}_S^- , the following expression can be devised for the generalized forces at the tip of the virtual sticks

$$\mathbf{h}_S = \mathbf{W}_S^- \mathbf{h}_E + \mathbf{V}_S \mathbf{h}'_1, \quad (39.55)$$

where

$$\mathbf{W}_S^- = \begin{pmatrix} \mathbf{L} \\ \mathbf{I}_6 - \mathbf{L} \end{pmatrix}^T, \quad (39.56)$$

and the matrix \mathbf{L} is the so-called load sharing matrix. It can be easily proved that the nondiagonal elements of \mathbf{L} only yield a \mathbf{h}_S vector in the null space of \mathbf{W}_S , that is, the space of internal forces/moments. Therefore, without losing generality, let us choose \mathbf{L} such that

$$\mathbf{L} = \text{diag}\{\boldsymbol{\lambda}\}, \quad (39.57)$$

where the vector $\boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_6)^T$ collects a set of constants λ_i representing the load-sharing coefficients.

The problem is that of properly tuning the load-sharing coefficients to ensure correct cooperative manipulation of the object by the arms. In order to answer this question, it must be noticed that, by combining equations (39.11) and (39.55), the following relation can be obtained

$$\mathbf{h}_1 = \mathbf{V}_S^+ (\mathbf{W}_S^- - \mathbf{W}_S^+) \mathbf{h}_E + \mathbf{h}'_1, \quad (39.58)$$

which, bearing in mind that only \mathbf{h}_E and \mathbf{h}_S are really existing forces/moments, indicates that:

- \mathbf{h}_I , \mathbf{h}'_I , and λ_i can be thought of as *artificial* parameters, introduced for better understanding of the manipulation process.
- \mathbf{h}'_I and λ_i are not independent; the concept of internal forces/moments and the concept of load sharing are mathematically mixed with each other.

Therefore, tuning the load-sharing coefficients or choosing suitable internal forces/moments is strictly equivalent from the mathematical (and, also, from the performance) point of view. Only one variable among \mathbf{h}_I , \mathbf{h}'_I , and λ is independent; hence, any of those redundant parameters, to be optimized for load sharing, can be exploited. This is more generally stated in [39.39, 40]. In [39.42], internal forces/moments \mathbf{h}_I are tuned, both for the sake of simplicity and for consistency with the adopted control laws.

A very relevant problem related to load sharing is that of robust holding, i.e., the problem of determining forces/moments applied to object by the arms, \mathbf{h}_S , required to keep the grasp even in the presence of disturbing external forces/moments. This problem can be solved by tuning the internal forces/moments (or the load-sharing coefficients, of course) and is addressed, e.g., in [39.41], where conditions to keep the grasp are expressed via end-effector forces/moments. Namely, by replacing \mathbf{h}_S in (39.55) into the equations expressing the grasp conditions, a set of linear inequalities for both \mathbf{h}'_I and λ are obtained

$$\mathbf{A}_L \mathbf{h}'_I + \mathbf{B}_L \lambda < \mathbf{c}_L, \quad (39.59)$$

39.5 Task-Space Analysis

As for single-arm robotic systems, a major issue in cooperative manipulation is that of task-space performance evaluation via the definition of suitable manipulability ellipsoids. These concepts have been extended to multi-arm robotic systems in [39.31]. Namely, by exploiting the kinetostatic formulation in Sect. 39.3, velocity and force manipulability ellipsoids are defined by regarding the whole cooperative system as a mechanical transformer from the joint space to the cooperative task space. Since the construction of force/velocity ellipsoids involves nonhomogeneous quantities (i.e., forces and moments, linear and angular velocities), special attention must be paid to the definition of such concepts [39.14, 70, 71]. Also, as for the ellipsoids involving internal forces, a major issue is that of physically meaningful parametrization of the internal forces (see, e.g., the work in [39.15, 16]).

where \mathbf{A}_L and \mathbf{B}_L are 6×6 matrices and \mathbf{c}_L is a (6×1) vector. In [39.41], a solution λ for the inequality is obtained heuristically. The above inequality can be transformed into another inequality expressed with respect to \mathbf{h}_I , of course; however, λ is fitter to such heuristic algorithm because it can be understood intuitively. The same problem may be solved mathematically, by introducing an objective function to be optimized; in this way, the problem is recast in the framework of mathematical programming. To this purpose, let us choose a quadratic cost function of \mathbf{h}_I to be minimized

$$f = \mathbf{h}_I^T \mathbf{Q} \mathbf{h}_I, \quad (39.60)$$

where \mathbf{Q} is a (6×6) positive-definite matrix. The above cost function can be seen as a (pseudo)energy to be dissipated by the joint actuators: i.e., the arms dissipate electrical energy in the actuators to yield the internal forces/moments \mathbf{h}_I . A solution to the quadratic programming problem (39.60) can be found, e.g., in [39.42].

For further insights on the problem of robust holding in the framework of multifingered manipulation, the reader is referred to Chap. 38.

Interestingly, in [39.37] the problem of load distribution is formulated in such a way to take into account manipulators dynamics at the joint level. This approach allows the expression of the load-sharing problem directly in terms of joints actuators torques; at this level, different subtask performance indexes can be used, in a similar way as was done to solve the inverse kinematics of redundant manipulators, to achieve load distribution solutions.

In detail, by following the approach in [39.31], the *external force manipulability ellipsoid* can be defined by the following scalar equation

$$\mathbf{h}_E^T (\mathbf{J}_E \mathbf{J}_E^T) \mathbf{h}_E = 1, \quad (39.61)$$

where $\mathbf{J}_E = \mathbf{W}^{\dagger T} \mathbf{J}$. The *external velocity manipulability ellipsoid* is defined dually by the following scalar equation

$$\mathbf{v}_E^T (\mathbf{J}_E \mathbf{J}_E^T)^{-1} \mathbf{v}_E = 1. \quad (39.62)$$

In the case of dual-arm systems the *internal force manipulability ellipsoid* can be defined as

$$\mathbf{h}_I^T (\mathbf{J}_I \mathbf{J}_I^T) \mathbf{h}_I = 1, \quad (39.63)$$

where $\mathbf{J}_I = \mathbf{V}^T \mathbf{J}$. Also, the *internal velocity ellipsoid* can be defined, via kinetostatic duality, as

$$\mathbf{v}_I^T (\mathbf{J}_I \mathbf{J}_I^T)^{-1} \mathbf{v}_I = 1. \quad (39.64)$$

The internal force/velocity ellipsoids can be defined in the case of cooperative systems composed of more than two manipulators by considering one pair of interacting end-effectors at a time [39.31].

The manipulability ellipsoids can be seen as performance measures aimed at determining the arms' attitude to cooperate in a given system's configuration. Also, as for the single-arm systems, the manipulability

ellipsoids can be used to determine optimal postures for redundant multi-arm systems.

Besides the above described approach, two other main approaches have been proposed to analyze the manipulability of cooperative multi-arm systems: the task-oriented manipulability measure [39.32] and polytopes [39.33]. Moreover, in [39.34] a systematic approach to perform dynamic analysis of multi-arm systems is presented. Namely, the concept of dynamic manipulability ellipsoid is extended to multi-arm systems, and indexes of the system's capability of generating object accelerations along assigned task-space directions are devised.

39.6 Control

When a cooperative multi-arm system is employed for the manipulation of a common object, it is important to control both the absolute motion of the held object and the internal stresses applied to it. Hence, most of the control approaches to cooperative robotic systems can be classified as force/motion control schemes, in that they decompose the control action in a motion control loop, aimed at tracking of the desired object motion, and a force control loop, aimed at controlling the internal loading of the object.

Early approaches to the control of cooperative systems are based on the *master/slave* concept [39.2]. Namely, the cooperative system is decomposed into:

- A master arm, which is in charge of imposing the absolute motion of the object; hence, the master arm is position controlled so as to achieve accurate and robust tracking of position/orientation reference trajectories, in the face of external disturbances (e.g., forces due to the interaction with the other cooperating arms); in other words, the master arm is controlled so as to have a *stiff* behavior.
- The slave arms, which are force controlled so as to achieve a *compliant* behavior with respect to the interaction forces; hence, it is expected that the slave arms are capable of following (as smoothly as possible) the motion imposed by the master arm.

A natural evolution of the above approach is the so-called *leader-follower* [39.67], where the follower arms reference motion is computed via closed-chain constraints.

However, such approaches suffered from implementation issues, mainly due to the fact that the compliance of the slave arms has to be very large, so as to follow the motion imposed by the master arm smoothly. Also, a difficulty arises when the roles of master and

slave have to be assigned to the arms for a given cooperative task, since the master/slave modes may need to be dynamically changed during the task execution.

Hence, a more natural non-master/slave approach has been pursued later, where the cooperative system is seen as a whole. Namely, the reference motion of the object is used to determine the motion of all the arms in the system and the interaction forces acting at each end-effector are fed back so as to be directly controlled. To this aim, the mappings between the forces and velocities at the end-effector of each manipulator and their counterparts at the manipulated object are to be considered in the design of the control laws.

39.6.1 Hybrid Control

In [39.11, 12] a non-master/slave approach has been proposed, based on the well-known scheme proposed by Raibert and Craig for the robot/environment interaction control of single-arm systems (Chap. 9). The operational space vector for the hybrid position/force control is defined via the following variables

$$\mathbf{x}_O = \begin{pmatrix} \mathbf{x}_E \\ \mathbf{x}_I \end{pmatrix}, \quad (39.65)$$

where \mathbf{x}_E , \mathbf{x}_I are the operational space vectors, defined by specifying the orientation via a minimal set of orientation angles (e.g., Euler angles). The generalized forces vector to be considered is

$$\mathbf{h}_O = \begin{pmatrix} \mathbf{h}_E \\ \mathbf{h}_I \end{pmatrix}. \quad (39.66)$$

The organization of the control scheme is shown diagrammatically in Fig. 39.2. The suffixes d and m

Fig. 39.2 A hybrid position/force control scheme

represent the desired value and the control command, respectively. The command vector τ_m to the actuators of the two arms is given by two contributions

$$\tau_m = \tau_p + \tau_h. \quad (39.67)$$

The first term, τ_p , is the command vector for the position control and is given by

$$\tau_p = K_x J_s^{-1} G_x(s) S B(x_{O,d} - x_o), \quad (39.68)$$

while τ_h is the command vector for the force control

$$\tau_h = K_h J_s^T G_h(s) (I - S)(h_{O,d} - h_o). \quad (39.69)$$

The matrix B transforms the errors on the orientation angles into equivalent rotation vectors. The matrix J_s is the Jacobian matrix that transforms the joint velocity \dot{q} into the task-space velocity v_o . The matrix operators $G_x(s)$ and $G_h(s)$ represent position and force control laws, respectively. The gain matrices K_x and K_h are assumed to be diagonal; their diagonal elements convert velocity and force commands into actuator commands, respectively. The matrix S selects the position-controlled variables; it is diagonal and its diagonal entries take the values of 1 or 0; namely, the i -th workspace coordinate is position controlled if the i -th diagonal element of S is 1, while it is force controlled if it is 0. Finally, I is the identity matrix having the same dimensions as S , while q and h are the vectors of measured joint variables and measured end-effector generalized forces, respectively.

39.6.2 PD Force/Motion Control

In [39.17] a Lyapunov-based approach is pursued to devise force/position PD-type control laws. Namely, the joints torques inputs to each arm are computed as the combination of two contributions

$$\tau_m = \tau_p + \tau_h, \quad (39.70)$$

where τ_p is a PD-type term (eventually including a feedback/feedforward model-based compensation

term), taking care of position control, while τ_h is in charge of internal forces/moments control.

Namely, the PD and model-based terms can be computed at the joint level

$$\tau_p = K_p e_q - K_d \dot{q} + g + J^T W^\dagger g_E, \quad (39.71)$$

where $e_q = q_d - q$, q_d is the vector of desired joint variables, K_p and K_d are positive-definite matrix gains, g is the vector of the gravitational forces/torques acting at the manipulators joints, g_E is the vector of gravity forces/moments at the manipulated object.

Since the cooperative task is usually assigned in terms of absolute and relative motion, the equivalent end-effector desired trajectories are to be computed by using the closed-chain constraints, as in the following example.

Example 39.2 (Computation of Desired Trajectories for a Planar Two-Arm System)

For the planar two-arm system, the desired trajectories defining the cooperative task are assigned by specifying the absolute, $x_{a,d}(t)$, and relative, $x_{r,d}(t)$, desired motion. Then, the corresponding end-effectors desired trajectories can be computed as

$$x_{1,d}(t) = x_{a,d}(t) - \frac{1}{2} x_{r,d}(t), \quad (39.72)$$

$$x_{2,d}(t) = x_{a,d}(t) + \frac{1}{2} x_{r,d}(t), \quad (39.73)$$

where (39.41) and (39.42) have been exploited.

In the spatial case (39.72) and (39.73) do not hold, since the absolute and relative orientation must be expressed in terms of geometrically meaningful quantities, e.g., via (39.44) and (39.45). However, the same approach may be pursued at the expense of a slightly more complex expressions of the above formulas [39.26].

Once, the desired position/orientation for each end-effector has been obtained, the inverse kinematics of each arm has to be computed to provide the desired joint trajectories, q_d , to the control loop; to this aim, e.g., numerical inverse kinematics algorithms may be employed (Chaps. 2 and 10).

Also, a PD-type control law can be expressed in terms of end-effector variables, i.e.,

$$\tau_p = J^T (K_p e - K_v v) - K_d \dot{q} + g + J^T W^\dagger g_E, \quad (39.74)$$

where e is the tracking error computed in terms of end-effector position/orientation variables, v is the vector

collecting the end-effector velocities, and \mathbf{K}_p , \mathbf{K}_v , and \mathbf{K}_d are positive-definite matrix gains.

Finally, the same concept may be exploited to design a PD control law directly in the object space

$$\tau_p = \mathbf{J}^T \mathbf{W}^\dagger (\mathbf{K}_p \mathbf{e}_E - \mathbf{K}_v \mathbf{v}_E) - \mathbf{K}_d \dot{\mathbf{q}} + \mathbf{g} + \mathbf{J}^T \mathbf{W}^\dagger \mathbf{g}_E, \quad (39.75)$$

where \mathbf{e}_E is the tracking error computed in terms of object absolute position/orientation variables, \mathbf{v}_E is the object's generalized velocity vector, and \mathbf{K}_p , \mathbf{K}_v , and \mathbf{K}_d are positive-definite matrix gains.

The internal force control term can instead be designed as follows

$$\tau_h = \mathbf{J}^T \mathbf{V} \mathbf{h}_{I,c}, \quad (39.76)$$

where

$$\mathbf{h}_{I,c} = \mathbf{h}_{I,d} + \mathbf{G}_h(s)(\mathbf{h}_{I,d} - \mathbf{h}_I), \quad (39.77)$$

$\mathbf{G}_h(s)$ is a matrix operator representing a strictly proper linear filter, such that $\mathbf{I} - \mathbf{G}_h(s)$ has zeros only in the left half plane, and $\mathbf{h}_{I,d}$ is the vector of desired internal forces; the internal force vector can be computed from the vector of measured end-effector forces as $\mathbf{h}_I = \mathbf{V}^\dagger \mathbf{h}$. A particularly simple choice, ensuring a null error at steady state, is given by

$$\mathbf{G}_h(s) = \frac{1}{s} \mathbf{K}_h,$$

where \mathbf{K}_h is a positive-definite matrix. Remarkably, when an infinitely rigid object/grasp is considered, preprocessing of the force error via a strictly proper filter is needed to ensure closed-loop stability [39.17]; e.g., if a simple proportional feedback is adopted (i.e., $\mathbf{G}_h(s) = \mathbf{K}_h$), the closed loop will be unstable in the presence of an arbitrary small time delay, unless a small (namely, smaller than 1) force gain is adopted. In practice, the closed kinematic chain will be characterized by some elasticity (e.g., due to grippers, end-effector force/torques sensors, joints); in this case, the product between the control gain \mathbf{K}_h and the stiffness of the flexible components has to be chosen sufficiently small to ensure stability.

An interesting extension of the above approach has been given in [39.26, 28], where kinetostatic filtering of the control action is performed so as to filter all the components of the control input which contribute to internal stresses at the object. Namely, the control law (39.71) can be modified by weighting the proportional term ($\mathbf{K}_p \mathbf{e}_q$) via the filtering matrix

$$\phi = \mathbf{J}^T (\mathbf{W}^\dagger \mathbf{W} + \mathbf{V} \Sigma \mathbf{V}^\dagger) \mathbf{J}^{-T},$$

where the (6×6) diagonal matrix $\Sigma = \text{diag}\{\sigma_i\}$ weights the components of $\mathbf{J}^{-T} \mathbf{K}_p \mathbf{e}_q$ in each direction of the subspace of the internal forces via the constant values $0 \leq \sigma_i \leq 1$. In detail, if $\Sigma = \mathbf{O}_6$ then all these components are completely canceled from the control action, while the choice $\Sigma = \mathbf{I}_6$ leads to the control law (39.71) without kinetostatic filtering. In a similar way, the control laws (39.74) and (39.75) can be modified so as to introduce proper kinetostatic filtering of $\mathbf{K}_p \mathbf{e}$ and $\mathbf{K}_p \mathbf{e}_E$, respectively.

39.6.3 Feedback Linearization Approaches

A further improvement of the PD-plus-gravity compensation control approach has been achieved by introducing a full model compensation, so as to achieve feedback/feedforward linearization of the closed-loop system. The feedback linearization approach formulated at the operational space level is the base for the so-called *augmented object* approach [39.72, 73]. In this approach the system is modeled in the operational space as a whole, by suitably expressing its inertial properties via a single augmented inertia matrix \mathbf{M}_O . Hence, the dynamics of the cooperative system in the operational space can be written as

$$\mathbf{M}_O(\mathbf{x}_E) \ddot{\mathbf{x}}_E + \mathbf{c}_O(\mathbf{x}_E, \dot{\mathbf{x}}_E) = \mathbf{h}_E. \quad (39.78)$$

In (39.78), \mathbf{M}_O and \mathbf{c}_O are the operational space terms modeling, respectively, the inertial properties of the whole system (manipulators and object) and the Coriolis, centrifugal, friction, and gravity terms.

In the framework of feedback linearization (formulated in the operational space), the problem of controlling the internal forces can be solved, e.g., by resorting to the *virtual linkage* model [39.16] or according to the scheme proposed in [39.29], i.e.,

$$\begin{aligned} \tau = \mathbf{J}^T \mathbf{W}^\dagger [& \mathbf{M}_O (\ddot{\mathbf{x}}_{E,d} + \mathbf{K}_v \dot{\mathbf{e}}_E + \mathbf{K}_p \mathbf{e}_E) + \mathbf{c}_O] \\ & + \mathbf{J}^T \mathbf{V} \left[\mathbf{h}_{I,d} + \mathbf{K}_h \int (\mathbf{h}_{I,d} - \mathbf{h}_I) \right]. \end{aligned} \quad (39.79)$$

The above control law yields a linear and decoupled closed-loop dynamics

$$\begin{aligned} \ddot{\mathbf{e}}_E + \mathbf{K}_v \dot{\mathbf{e}}_E + \mathbf{K}_p \mathbf{e}_E &= \mathbf{0}, \\ \ddot{\mathbf{h}}_I + \mathbf{K}_h \int \tilde{\mathbf{h}}_I dt &= \mathbf{0}, \end{aligned} \quad (39.80)$$

where $\tilde{\mathbf{h}}_I = \mathbf{h}_{I,d} - \mathbf{h}_I$. Hence, the closed-loop dynamics guarantees asymptotically vanishing motion and force errors.

39.6.4 Impedance Control

An alternative control approach can be pursued based on the well-known impedance concept (Chap. 9). In fact, when a manipulation system interacts with an external environment and/or other manipulators, large values of the contact forces and moments can be avoided by enforcing a compliant behavior, with suitable dynamic features, of the robotic system. Impedance control schemes have been proposed in the case of cooperative manipulation to control object/environment interaction forces [39.21] or internal forces [39.22]. More recently, an impedance scheme for the control of both external forces and internal forces has been proposed [39.74] (in  VIDEO 67 some experimental results of impedance control at a dual-arm cooperative system are documented).

In detail, the impedance scheme in [39.21] enforces the following mechanical impedance behavior between the object displacements and the forces acting on object due to interaction with the environment

$$\mathbf{M}_E \ddot{\mathbf{a}}_E + \mathbf{D}_E \dot{\mathbf{v}}_E + \mathbf{K}_E \mathbf{e}_E = \mathbf{h}_{\text{env}}, \quad (39.81)$$

where:

- \mathbf{e}_E represents the vector of the object's displacements between the desired and actual pose
- $\dot{\mathbf{v}}_E$ is the difference between the object's desired and actual generalized velocities
- $\ddot{\mathbf{a}}_E$ is the difference between the object's desired and actual generalized accelerations,

and \mathbf{h}_{env} is the generalized force acting on object due to the interaction with the environment. The impedance dynamics is characterized in terms of given positive-definite mass (\mathbf{M}_E), damping (\mathbf{D}_E), and stiffness (\mathbf{K}_E) matrices to be properly chosen so as to achieve the desired compliant behavior of the object.

As for the pose displacements used in (39.81), special attention has to be paid to the orientation variables.

Example 39.3 (External Impedance for a Planar Two-Arm System)

For the planar two-arm system the quantities in (39.81) can be defined in a straightforward way. Namely,

$$\mathbf{e}_E = \mathbf{x}_{E,d} - \mathbf{x}_E, \quad (39.82)$$

$$\dot{\mathbf{v}}_E = \dot{\mathbf{x}}_{E,d} - \dot{\mathbf{x}}_E, \quad (39.83)$$

$$\ddot{\mathbf{a}}_E = \ddot{\mathbf{x}}_{E,d} - \ddot{\mathbf{x}}_E, \quad (39.84)$$

where \mathbf{x}_E is the (3×1) vector collecting the object's position and the orientation, while $\mathbf{x}_{E,d}$ represents its desired counterpart. Hence, \mathbf{M}_E , \mathbf{D}_E , and \mathbf{K}_E are (3×3) matrices.

In the spatial case, orientation displacements cannot be defined as in (39.82), and geometrically meaningful orientation representations (i.e., rotation matrices and/or angle/axis representations) or in terms of operational space variables (i.e., differences between operational space vectors) have to be adopted [39.74].

The impedance scheme in [39.22], enforces a mechanical impedance behavior between the i -th end-effector displacements and the internal forces, i.e.,

$$\mathbf{M}_{I,i} \ddot{\mathbf{a}}_i + \mathbf{D}_{I,i} \dot{\mathbf{v}}_i + \mathbf{K}_{I,i} \mathbf{e}_i = \mathbf{h}_{I,i}, \quad (39.85)$$

where:

- \mathbf{e}_i is the vector expressing the displacement of the i -th end-effector between the desired and actual pose
- $\dot{\mathbf{v}}_i$ is the vector expressing the difference between the desired and actual velocities of the i -th end-effector
- $\ddot{\mathbf{a}}_i$ is the vector expressing the difference between the desired and actual accelerations of the i -th end-effector,

and $\mathbf{h}_{I,i}$ is the contribution of the i -th end-effector to the internal force, i.e., the i -th component of the vector $\mathbf{V}\mathbf{V}^\dagger \mathbf{h}$. Again, the impedance dynamics is characterized in terms of given positive-definite mass ($\mathbf{M}_{I,i}$), damping ($\mathbf{D}_{I,i}$), and stiffness ($\mathbf{K}_{I,i}$) matrices, to be properly chosen so as to achieve a suitable compliant behavior of the end-effectors with respect to internal forces.

Example 39.4 (Internal Impedance for a Planar Two-Arm System)

For the planar two-arm system the quantities in (39.85) can be defined in a straightforward way as well

$$\mathbf{e}_i = \mathbf{x}_{i,d} - \mathbf{x}_i, \quad (39.86)$$

$$\dot{\mathbf{v}}_i = \dot{\mathbf{x}}_{i,d} - \dot{\mathbf{x}}_i, \quad (39.87)$$

$$\ddot{\mathbf{a}}_i = \ddot{\mathbf{x}}_{i,d} - \ddot{\mathbf{x}}_i, \quad (39.88)$$

where \mathbf{x}_i is the (3×1) vector collecting the position in the plane and the orientation angle of the i -th end-effector, while $\mathbf{x}_{i,d}$ represents its desired counterpart. Again, $\mathbf{M}_{I,i}$, $\mathbf{D}_{I,i}$, and $\mathbf{K}_{I,i}$ are (3×3) matrices.

As for the spatial case, orientation displacements in (39.85) cannot be defined as in (39.86), and geometrically meaningful orientation representations (i.e., rotation matrices and/or angle/axis representations) or in terms of operational space variables (i.e., differences between operational space vectors) have to be adopted [39.74].

The above two approaches have been combined in [39.74], where two control loops are designed to enforce an impedance behavior both at the object level (external forces) and at the end-effector level (internal forces).

39.7 Conclusions and Further Reading

In this chapter, the fundamentals of cooperative manipulation have been presented. A historical overview of the research on cooperative manipulation has been provided. The kinematics and dynamics of robotic arms cooperatively manipulating a tightly grasped rigid object are considered. Special topics, such as the definition of a cooperative task space and the problem of load distribution, have also been touched on. Then, the main control approaches for cooperative systems have been discussed. A few advanced topics related to control of cooperative robots, i.e., advanced nonlinear control as well as the modeling and control of cooperative systems including flexible elements, will be briefly outlined in the following.

Some of the first attempts to cope with uncertainties and disturbances in cooperative robots control focused on adaptive strategies [39.23, 24], in which the unknown parameters are estimated online, based on a suitable linear-in-the-parameters model of the uncertainties. In detail, the approach in [39.23] is aimed at controlling the object motion, the interaction force due to the contact object/environment, and the internal forces; the adaptive control law estimates the unknown model parameters, both of the manipulators and of the object, on the basis of suitable error equations. In [39.24], the adaptive control concept is used to design a decentralized scheme, i.e., a centralized coordinator is not used, for redundant cooperative manipulators.

A recently developed control framework for cooperative systems is the so-called synchronization control [39.51, 52]; in this approach the control problem is formulated in terms of suitably defined errors accounting for motion synchronization between the manipulators involved in the cooperative task. Namely, the key idea in [39.51] is to ensure tracking of the desired trajectory assigned to each manipulator, while synchronizing its motion with other manipulators motion. In [39.52], the problem of synchronizing the motion of multiple manipulators systems is solved by using only position measurements; the synchronization controller consists of a feedback control law and a set of nonlinear observers, and synchronization is ensured by suitably defining the coupling errors between the manipulators' motions.

Recently, research efforts have been spent on intelligent control [39.53–55]. Namely, in [39.53], a semi-decentralized adaptive fuzzy control scheme, with \mathcal{H}_∞ performance in motion and internal force tracking, is proposed; the controller of each robot consists of two parts: a model-based adaptive controller and an adaptive fuzzy logic controller; the model-based adap-

tive controller handles the nominal dynamics, including a purely parametric uncertainties model, while the fuzzy logic controller is aimed at counteracting the effect of unstructured uncertainties and external disturbances. In [39.54], a decentralized adaptive fuzzy control scheme is proposed, where the control law makes use of a multi-input multi-output fuzzy logic engine and a systematic online adaptation mechanism. The approach has been further extended in [39.55].

Finally it is worth mentioning the efforts invested in the investigation of control strategies using partial state feedback, i.e., only joints position and end-effector forces are fed back to the controller. A recent contribution was provided by the work in [39.56], in which a decentralized control algorithm that achieves asymptotic tracking of desired positions and forces by using a nonlinear observer for velocities was proposed.

Flexibility in a cooperative system may arise, e.g., due to the use of nonrigid grippers to grasp the manipulated object. In fact, the adoption of compliant grippers allows large internal forces to be avoided and, at the same time, achieves safe manipulation of the object, even in the presence of failures and unpredicted contacts with the external environment. In detail, the work in [39.61] develops a non-model-based decentralized control scheme. Namely, a proportional–derivative (PD) position feedback control scheme with gravity compensation, is designed; the PD scheme is capable of regulating the position/orientation of the manipulated object and, simultaneously, achieves damping of the vibrations induced by the compliant grippers; also, a hybrid scheme is adopted to control internal forces along the directions in which the compliance of grippers is too low to ensure limited internal stresses at the manipulated object.

Other research efforts have been focused on handling multibodied objects, or even flexible objects [39.43–45]. Those objects are difficult to handle and, therefore, assembly of those objects in manufacturing industry is not automated. Also, cooperative control of multi-flexible-arm robots has been investigated [39.46–48]. Once the modeling and control problem is solved (Chap. 11), the flexible-arm robot is a robot with many merits [39.49]: it is lightweight, compliant, and hence safe, etc. Combining control methods for flexible-arm robots, such as vibration suppression, with the cooperative control methods presented in this chapter is straightforward [39.46]. Automated object-retrieval operation with a two-flexible-arm robot has been demonstrated in [39.47, 48] and in  VIDEO 68.

Finally, cooperative transportation and manipulation of objects via multiple mobile manipulators

can be considered still an open research subject. In fact, although notable research results have been already devised [39.65, 75–77], the foreseen use of robotic teams in industrial settings (hyperflexible robotic workcells) and/or in collaboration with humans (robotic co-worker concept) raises new chal-

lenges related to autonomy and safety of such systems. A recently emerged application scenario is the cooperative transportation of objects via multiple aerial robots [39.66] (see  VIDEO 66 for an example of cooperative transportation via multiple unmanned aerial vehicles).

40. Mobility and Manipulation

Oliver Brock, Jaeheung Park, Marc Toussaint

Mobile manipulation requires the integration of methodologies from all aspects of robotics. Instead of tackling each aspect in isolation, mobile manipulation research exploits their interdependence to solve challenging problems. As a result, novel views of long-standing problems emerge. In this chapter, we present these emerging views in the areas of grasping, control, motion generation, learning, and perception. All of these areas must address the shared challenges of high-dimensionality, uncertainty, and task variability. The section on grasping and manipulation describes a trend towards actively leveraging contact and physical and dynamic interactions between hand, object, and environment. Research in control addresses the challenges of appropriately coupling mobility and manipulation. The field of motion generation increasingly blurs the boundaries between control and planning, leading to task-consistent motion in high-dimensional configuration spaces, even in dynamic and partially unknown environments. A key challenge of learning for mobile manipulation consists of identifying the appropriate priors, and we survey recent learning approaches to perception, grasping, motion, and manipulation. Finally, a discussion of promising methods in perception shows how concepts and methods from navigation and active perception are applied.

What exactly is mobile manipulation? To find an answer to this question, we must consider the historical development of this research area. The term mobile manipulation was coined in the late 1980s to early 1990s, when research labs began to mount robot manipulators on mobile platforms [40.1, 2]. Back then, the term was intended to capture just that: research was conducted on an experimental platform that combines capabilities in

mobility and manipulation. A series of mobile manipulation platforms is shown in Fig. 40.1.

With the introduction of such platforms it soon became apparent that combining mobility with manipulation was a game changer. Mobility enables manipulators to leave the lab. They now have to face the complexities of the real world. And in the real world, much of the research that had been successful in the carefully

controlled environments in research labs proved to be brittle or inadequate. This traditional research often relied on strong assumptions about the environment to be successful – an untenable assumption in unpredictable, nonstationary everyday environments.

In the context of mobile manipulation research, controlled environments, such as factory floors and specific experimental setups, are often referred to as *structured environments*. In contrast, *unstructured environments* are environments that have not been modified specifically to facilitate the execution of a task by a robot. These two types of environments are opposites on a continuous scale with many possible intermediates. And, of course, structured environments are still laden with uncertainty just the same as unstructured environments still contain a significant structure that can be exploited by the robot.

In unstructured environments, it becomes a necessity for the robot to perform a wide variety of tasks, instead of a single specific task. Any specific task, such as retrieving a book from the library, might require the robot to solve additional challenges, such as opening doors, operating elevators, moving a chair out of the way to approach the shelf, or asking for the location of the stacks. Today, no robotic system possesses such capabilities.

Researchers in mobile manipulation have learned that the progress achieved in traditional research areas of robotics cannot simply be combined to produce the level of competency they aim for. This insight motivated the founding of mobile manipulation as a research area. The research in this area seeks to develop robotic systems capable of autonomous task execution in unstructured or minimally structured environments. Clearly, the transition from single-purpose lab demonstration – a common practice in robotics – toward such

mobile manipulation systems is a gradual one. Mobile manipulation research therefore gradually increases the autonomy, robustness, and task generality of robotic systems, while at the same time gradually reducing the dependence on prior information about the environment and the task.

The objective of mobile manipulation research is to:

1. Maximize task generality of autonomous robotic systems, while at the same time
2. Minimizing the dependence on task-specific, hard-coded, or narrowly-relevant information.

Some people argue that this is exactly what main stream robotics is doing and what most of this Handbook is about. And they might be right. But over the last 20 years, the mobile manipulation community, forced by failures of robotic systems in the real world, has begun to explore alternatives and extensions to the body of robotics knowledge collected in this tome. It is these alternatives or extensions that this chapter is about. In each of the subsequent sections, our goal is to showcase work in mobile manipulation that opens up possible novel directions for future advances toward robots operating in real-world environments. For the areas of grasping and manipulation, mobility, control, motion generation, learning, and perception, we will analyze how the main challenges of the field change when systems are operating in the real world. We will show how each of these fields has developed and advanced to increasingly address the challenges of unstructured environments.

Before we embark on this journey, it is worthwhile to agree on the challenges that are in fact encountered when robots are supposed to perform a variety of tasks in an unconstrained and uncontrolled envi-

Fig.40.1a–d Some exemplary mobile manipulation platforms developed throughout the decades (a) Herbert (MIT, 1985), (b) Stanford assistant mobile manipulator (1995), (c) PR2 (Willow Garage, 2009), (d) Herb (CMU, 2013)

ronment. These challenges are common to all of the subdisciplines we discuss in the following sections.

First, the necessity to perform a variety of tasks, instead of a single one, requires that the robot be equipped with general means of mobility, manipulation, and perception. Its capabilities must be the union of the minimum capabilities required for each task. This entails the need for versatile sensing and dexterous manipulation. This, in turn, implies that the sensor input of the robot is high dimensional and so is the configuration space of the robot. The first challenge therefore consists of dealing with the *high dimensionality* and the inherent complexity of the state spaces required for task generality. To make matters worse, task generality most often requires system dynamics to be hybrid, i. e., exhibit discrete as well as continuous behavior.

Second, by the definition of mobile manipulation, the robot cannot rely on a complete, continuously, and globally updated world model. While some part of the robotics community attempts to structure the world to become such a world model – by using RFID tags or by placing sensors everywhere – many in the mobile manipulation community believe it to be more effective and more insightful to make robots smarter. Not having a complete world model means that the robot has to use perception to acquire relevant information about

the world; it means that the robot has to address the uncertainty in its sensing, but also the uncertainty in its world model which might change unbeknownst to the robot. The second challenge therefore consists of appropriately handling the *uncertainty* inherent to sensing and actuation and the uncertainty caused by a dynamic world.

Third, in the real world, objects exhibit large variability from the perspective of their appearance, even when they perform exactly the same function. This means that there is a layer of indirection through appearance when a robot wants to operate autonomously in the real world. There are so many different kinds of door handles, they differ significantly in appearance, but perform the same function. The challenge therefore is to cope with the *variability* in the world by revealing the functional principles underlying the world's appearance. A natural way of addressing variability are skills that generalize to novel situations.

As we will see in subsequent sections, attempts to address these challenges by the robotics community have produced innovative and successful concepts, algorithms, mechanisms, and integrated systems. Some of them were not covered in previous chapters, as they do not (yet?) belong to the canon of robotic wisdom. Maybe this chapter can contribute to changing this.

40.1 Grasping and Manipulation

Robots accomplish tasks by grasping, manipulating, and placing objects. Several chapters in this Handbook are concerned with associated mechanisms, methods, and concepts: Chapter 19 discusses robot hands, the most versatile type of end-effector for grasping and manipulation. Chapter 37 discusses manipulation in general and Chap. 38 presents the state of the art in grasping. Important for grasping and manipulation are also force and tactile sensors, which are discussed in Chap. 28. While these four chapters describe the well-established foundation of grasping and manipulation, in this chapter we want to take a higher level perspective, assess the suitability of these approaches in the context of mobile manipulation, and speculate about possible novel approaches.

Both grasping and manipulation exemplify the challenges for mobile manipulation we laid out above: uncertainty, high dimensionality, and task variability. Uncertainty is relevant as minor inaccuracies in the object model, minor errors in motion execution, and small differences in positioning relative to the object can cause grasp failure. The high dimensionality of grasping results from the many degrees of freedom of the hand as well as from those of the objects

in the environment. Finally, grasping and manipulation occur in a large number of variations, each involving vastly different interactions with objects. It is therefore not surprising that decades of research on grasping and manipulation have made significant progress but so far were unable to create skills sufficiently robust for autonomous operation in the real world.

In this section, we describe a recent development in the field of grasping and manipulation away from the foundational techniques laid out elsewhere in this Handbook toward novel approaches that seem better suited for addressing the manipulation challenges in mobile manipulation.

40.1.1 Problem Description

First, a word on defining the problem. Traditionally, grasping and manipulation are viewed as two distinct problems. But there is significant ambiguity with respect to these terms in the literature [40.3]. In this section, we limit ourselves to grasping and manipulation with robot hands. And in this context, we define the following terms:

Grasping refers to gaining reliable control over the extrinsic degrees of freedom of an object through the robot's degrees of freedom, i. e., the robot grasps an object so that it can change the object's extrinsic degrees of freedom by changing its own, excluding the degrees of freedom of the hand, which remain static once the grasp is achieved. To perform grasping, the overall degrees of freedom of the robot have traditionally been divided into two parts: those required to impart forces on an object (usually addressed using grasp planning approaches) and the remaining ones that can be used to reposition the object, once a grasp is obtained (general motion and manipulation planning). Note, however, that in contrast to this traditional decomposition, coordination of arm and hand degrees of freedom are usually required during grasping.

By *dexterous grasping* we refer to grasping while optimizing the grasp posture for (a) robustness and (b) suitability for the execution of a specific task. In the relevant literature, the overall degrees of freedom are still most commonly divided into those responsible for the grasp and those able to change the pose of the grasped object.

By *dexterous in-hand manipulation*, we refer to the ability to actuate the extrinsic degrees of freedom of the object using all degrees of freedom of the arm and the hand so that the object moves relative to a reference frame placed at the hand's wrist [40.4].

Classical approaches to all three of these problems rely on precise models of the environment and of the hand, carefully reason about contact points and states, and attempt to determine and precisely execute a detailed plan. We would like to point to the emergence of a novel approach to all three of these problems. Since this novel approach, however, has been mainly explored in the context of grasping at this early point in time, we will focus our discussion on grasping. But we will also make the point that in this new way of thinking about grasping and manipulation both of these problems become similar, if not identical.

40.1.2 Evaluation of the State of the Art

The earliest and still most fundamental considerations of grasping are based on the notions of force and form closure (Chap. 38).

Force and Form Closure

These notions express the effect of a set of disembodied contact points, i. e., ignoring the body on which that contact point lies, such as the finger, on the ability of an object to move. They reflect a static view of grasping, in which the physical interactions that will invariably occur during the grasp are not considered.

This line of research continues to be active and successful, as evidenced by a large number of sophisticated and capable grasp planners and simulators [40.5]. The resulting grasps, however, often do not result in successful real-world grasps. These failures are a consequence of model uncertainty and motion execution noise. The assumptions made during planning, i. e., that the disembodied contact points can be realized precisely by the hand, more often than not do not hold.

Interactions Between Hand and Object

There is a very simple strategy to overcome many of the theoretical failures of the approaches based on precise models and the notion of force closure – and this strategy is used tacitly by all grasping research: just keep closing the hand, even if you think you have attained the right configuration for your contact points. This strategy effectively leverages mechanical compliance of the hand to adapt the hand's configuration to the object's shape. This adaptation of shape has several positive effects for grasping:

1. Sensing and actuation uncertainty are compensated,
2. Large surface areas are established, and
3. Grasping forces are distributed and balanced.

These effects lead to an increase in grasp success and grasp quality. It is fair to say that this is a standard trick in the grasp planning community.

This insight is also strongly driving contemporary hand design. To maximize the effect of shape adaptation, *Rodriguez and Mason* [40.6] optimize finger shape to yield similar contact configuration irrespective of the size of the object. A different way of increasing shape adaptability is to include compliant components in the hand design [40.7]. The shape deposition manufacturing (SDM) hand [40.8], the Velo gripper [40.9], the i-HY hand [40.10], and the Pisa/IIT SoftHand [40.11] achieve shape adaptability through underactuation by coupling degrees of freedom of the hand, adapting the shape of the hand to the object while equalizing contact forces. An extreme case of this is the positive pressure gripper [40.12], which presses a bag filled with granular material onto the object to be grasped. The bag adapts to the shape of the object. When the air is evacuated from the bag, the granular material jams, forming a gripper perfectly adapted to the shape of the object.

From this brief analysis it is fair to say that the shape adaptability between hand and object is routinely leveraged in grasp planning, simply by *closing the hand* until a certain grasping force is reached. Also, shape adaptability has emerged as an important design criterion for hands, as it very obviously improves grasping performance.

Interactions Between Hand, Object, and Environment

Features in the environment, provided by other objects or support surfaces, for example, may constrain the motion of hand and object. This is most evident for support surfaces, such as tables and floors. These constraints, when used properly, can aid grasping. Furthermore, it might be the case that the necessary perceptual information for leveraging such constraints is often easier to obtain than the information required for the successful execution of an unconstrained grasp.

Recent research in robotic grasping leverages environmental constraints in the suggested manner, e.g., to position the hand relative to the object [40.13], to cage objects [40.13, 14], or to fixate an object during planar sliding [40.13, 15]. Some pregrasp manipulation relies on environmental constraints to improve grasp success. For example, *Chang et al.* [40.16] rotate pan handles into a specific orientation prior to grasping by exploiting the pan's friction and remote center of mass.

But, in addition to external contacts, environmental constraints can also be created by exploiting gravity, inertia, or dynamic motion of the arm and hand. In this way, in-hand manipulation is accomplished by using what has been called extrinsic dexterity [40.17].

All of the aforementioned grasp strategies rely on multiple interactions between hand, object, and environment prior to attaining the final grasp posture. These phases often are designed to reduce uncertainties in specific variables relevant to grasp success.

The idea of environmental constraints appears in early work by *Mason et al.* [40.18, 19]. Here, the intrinsic mechanics of the task environment are exploited to eliminate uncertainty and to achieve robustness.

The study of environmental constraint exploitation by humans so far has been limited to replicating instances of observed behavior on robots [40.16, 20]. For example, *Kaneko et al.* [40.20] extracted a set of grasping strategies from observations of a human subject. These strategies include interactions with environmental constraints.

We believe that this recent trend toward the exploitation of environmental constraints represents an important opportunity to improve robotic grasping capabilities. To take full advantage of this opportunity, we should understand the strategies humans employ, transfer them to robotic systems, and develop robotic hands tailored to this exploitation [40.21]. This will be discussed in the next section.

Insights from Human Grasping

Interestingly, the study of human grasping paralleled the development in the robotics community. Early stud-

ies of human grasping followed the static view captured by force closure concepts. This is reflected in grasp taxonomies, classifying grasp according to the final hand posture attained after the grasp process is completed [40.22, 23].

Even the early work on postural synergies, which has had a profound impact on robotics, initially only considered synergies of static grasp postures [40.24]. These studies do not capture the dynamic processes and the exploitation of environmental constraints we believe to be crucial for robust grasping. Nevertheless, these studies of human grasping have led to significant advances in robotic grasping [40.11].

The nature of hand-object interaction has also been studied in humans. The effect of shape adaptability is well known for human hands and studies have elucidated the degree to which humans vary their behavior to take advantage of it. *Christopoulos and Schrater* [40.25] showed that humans react to pose uncertainty of a cylinder and orient their hand to align it, presumably to be able to maximize the benefits of shape adaptability. However, other experiments may point at the fact that humans also rely on more complex interactions with the environment for grasping under difficult conditions. When the vision of humans is impaired, they fail more often at first grasp attempts of isolated (environmental-constraint free) objects [40.26]. The degree of the demonstrated effect seems surprising. We believe that in this specific experiment, it is due to the lack of environmental constraints exploitable for grasping.

More recently, studies of human grasping have shown the deliberate use of environmental constraints during grasping. For example, humans increase their use of environmental constraints when their vision is impaired [40.21]. This seems to indicate that the use of environmental constraints will play a crucial role in achieving robust and task-general grasping and manipulation in robotics.

Robot Hands

Many highly capable robotic hands exist. A historical overview, collecting robotic hands from over five decades, was compiled by *Controzzi et al.* [40.27]. An analysis of robot hand designs with respect to grasping capabilities was recently presented by *Grebenstein* [40.28]. As the notion of compliance is central to our hand design, we will limit our discussion to hands designs that deliberately include this concept.

We distinguish two main approaches for designing compliant hands. Compliance can be achieved using active control, and implemented on a fully actuated or even hyper-actuated systems, where every degree of freedom can be controlled. An impressive exam-

Fig.40.2a–e Various hand designs leveraging compliance to improve performance. (a) Awiwi hand (DLR), (b) SDM hand (Harvard), (c) Pisa-IIT hand, (d) i-HY hand (iRobot, Harvard, Yale), (e) RBO hand z (TU Berlin)

ple of this type of hand is the Awiwi hand [40.28], the ShadowRobot Shadow Dexterous Hand, and the SimLab Allegro Hand [40.29]. These hands achieve dexterity through accurate control, which comes at the price of mechanical complexity, making them difficult and costly to build and prone to failure.

An alternative approach is to make hands compliant by including elastic or flexible materials (passive compliance). Building a passively compliant joint is much cheaper than an actively controlled one, in terms of costs, volume and system complexity. Passive compliance can easily absorb impact forces – a desirable property for an end-effector designed to establish contact with the world. The cost of adding additional (passive) degrees of freedom is low, compared to actively compliant hands. The resulting ability to passively adapt to the shape of an object greatly enhances grasp success and grasp quality. At the same time, the hand can be under-actuated, effectively offloading control to the physical material.

A pioneering work in grasping with passive compliance was the soft gripper by Hirose and Umetani [40.7]. Recently, a whole range of grippers and hands were built using passive compliance, such as the FRH-4 hand [40.30], the SDM hand and its successor [40.10,

31, 32], the starfish gripper [40.33], the THE Second Hand and the Pisa-IIT Soft Hand [40.34], the Positive Pressure Gripper [40.12], the RBO Hands [40.13, 35], and the Velo Gripper [40.9]. A different source of inspiration was taken by Giannaccini et al. [40.36], who built an octopus-inspired compliant gripper. Some of these hands are shown in Fig. 40.2.

The practical realization of underactuated hands is matched by theoretical approaches to analyze and evaluate their dexterity [40.37, 38]. However, these approaches require accurate knowledge of grasp posture, contact point locations, and contact forces. Given today's sensor technologies, this information is difficult to obtain in physical implementations.

The inclusion of compliance into the design of robotic hands has led to significant improvements in power-grasping of objects. Given the insights obtained from human grasping (see the previous section), it is plausible that these improvements are the result of these hands' capabilities to engage in beneficial contact interactions with the environment. While these benefits have been demonstrated extensively in the context of power grasping, little work has examined the beneficial effects of compliance and underactuation on the dexterity of robotic hands [40.35].

40.1.3 Toward Robust Grasping and Manipulation

The key to robust grasping and manipulation – an important prerequisite for mobile manipulation – appears to be the deliberate and purposeful use of interactions between hand, object, and environment. This is supported by evidence from human grasping as well as from the design features of successful robotic hands. If this claim is true, it fundamentally changes the game in grasping and manipulation. The notion of a specific contact point configuration, which has for the last 50 years been of pivotal importance, is superseded by deliberate constraint exploitations. The traditional, static view of grasping is replaced with a dynamic view that

emphasizes motion of hand, object, and environment in contact with each other. Rather than placing fingers carefully at exactly the right place, this new way of thinking requires fingers to slide across surfaces, to comply to object shapes, and to balance and maintain contact forces through intelligent hardware design.

Especially in hardware design, there has been significant progress. The newest generation of hands are built for the exploitation of constraints: without sensing and explicit control, they support shape adaptation and compliant contact maintenance. One of the future challenges will be the development of grasp planning methods and perceptual capabilities to leverage the advantages afforded by these novel hands.

40.2 Control

Mobile manipulators are robotic systems with capabilities for both manipulation and mobility. A typical setup of mobile manipulator, therefore, consists of manipulator and mobile robot. Traditionally, mobile manipulators were implemented as wheeled mobile robots, providing mobility on two-dimensional flat surfaces. Mobility, however, can be provided by other types of robots depending on the operating environment. Legged robot systems operate well in uneven or rough terrain. Aerial or underwater robots allow operation in environments with totally different characteristics.

Controlling such mobile manipulators involves control for the subsystems. The control issues of manipulators are explained and discussed earlier in Chaps. 8 and 9. Modeling and control of various types of mobile

platforms will be introduced later in detail in Chaps. from 48 to 52 in Part E. In these chapters, we would like to discuss unique control problems in mobile manipulation, which arise when the manipulator and mobile platform operate simultaneously.

Control of mobile manipulators also has to address the three challenges we stated initially: high dimensionality, uncertainty, and task variability. The mobile manipulator was first implemented to provide mobility to the manipulator. One of the main purposes is to increase the manipulation workspace of the robot (Fig. 40.3). This mobile platform naturally adds more degrees of freedom to the system by providing mobility. The additional degrees of freedom increase the dimensionality of the control problem. The robot be-

Fig. 40.3a–c Increased workspace and redundancy of mobile manipulators. (a) A manipulator on a fixed base; (b) increased work space of a mobile manipulator; (c) redundancy due to the added mobility

comes a redundant system because the specified task to the robot is still the same, while the overall degrees of freedom have been increased. That is, there are infinite number of configurations that can execute the same task.

Second, uncertainty becomes severe in control of mobile manipulators due to the mobile platform. The uncertainty is larger when controlling a mobile platform compared to control of a manipulator. The reasons for the higher uncertainty are imperfect information or model about the operating environment, such as ground and underwater. Additionally mobile platforms with only internal sensors do not have access to perfect state information because drift raises uncertainty while moving. However, mobile manipulators need to solve the same manipulation tasks as stationary manipulators. They have to overcome this uncertainty to operate reliably.

Third, the variability of the mobile platform exists depending on the operating environment, although the high dimensionality and uncertainty are the common factors across the various mobile platforms. The different issues due to various mobile platforms are also to be discussed later in this chapter.

40.2.1 Problem Description

Control of mobile manipulators must provide capabilities for manipulation and mobility. Often times, these two are treated completely separate. The robot moves to a certain location using its mobile platform. Then, the manipulator performs specific tasks without moving the platform. In this approach, the mobile platform considers the manipulator as a static load. The mobile platform is then considered as a fixed base for the manipulator. There is no major difficulty implementing this approach, unless manipulator or mobile platform is unable to hold its position steadily.

The main problem to be discussed in this chapter arises when both manipulator and mobile base operate simultaneously. Although the previously mentioned approach of a separately controlling manipulator and a platform increases the workspace of the robot, it does not exploit the full capabilities of mobile platforms. Instead, the advantage of mobile manipulator can be maximized when the manipulator operates while the bases moves in coordination. This kind of operation will not only reduce the total operation time but will also increase task variability.

In this chapter, therefore, we will discuss how to control mobile manipulators by operating both subsystems at the same time. During this operation, the whole system becomes redundant due to the added degrees of freedom (DOF) from the mobile platform. How

to exploit this increased number of DOF is one important problem in mobile manipulation. Secondly, the increased uncertainty due to the mobile platform requires more robust control strategies than that only for manipulator. Finally, various issues for different types of mobile platforms will be discussed.

40.2.2 Evaluation of the State of the Art

First mobile manipulators were implemented as wheeled robots and wheels are still the most popular tool to enable a manipulator to move. Most of the issues that have been dealt with in wheeled mobile manipulator can be shared with other types of mobile platforms. Therefore, we start discussing wheeled mobile platforms in this chapter and discuss issues specific to other types of mobile platforms afterward.

Redundancy Resolution and Control

One of the main issues in controlling mobile manipulators has been how to use the additional DOFs to execute manipulation tasks in a stable way. An early study [40.39] investigated how to obtain solutions to the inverse kinematics problem that prevent the robot from tipping over.

Other approaches exploited the increased number of DOFs to avoid obstacles, increase manipulability, handle singularities, or achieve lower priority tasks. In [40.40], a preferred region to maximize the manipulability of the robotic arm is defined and the nonholonomic mobile platform is controlled to be within the region. The same concept of a preferred region is also applied to the force control of a mobile manipulator in [40.41]. These approaches are typical examples for approaches that coordinate with the manipulator and base motion, but control the subsystems separately.

The redundancy of mobile manipulators allows dealing with multiple tasks simultaneously. In the configuration approach [40.42, 43], additional tasks or specifications are defined to be simultaneously controlled with the end-effector. To obtain solutions online, a weighted damped least-squares approach was presented in [40.44]. The configuration approach is further developed to be used both for holonomic and nonholonomic bases in [40.45].

In [40.46], the unified control of the arm and holonomic base was achieved by applying the operational space control framework to the mobile manipulator. The coordination of the arm and base can be implemented in the null-space of the task control, which does not affect the control of the end-effector. Later, this approach was extended to deal with nonholonomic bases in [40.47]. It uses a complete model of the system with nonholonomic constraints to devise one unified con-

troller for the whole system. The redundancy was used to deal with internal and external constraints. Another model-based control is derived in [40.48] for a car-like and differentially-driven system.

Similarly, an approach of exploiting redundancy for avoiding singularities and maximizing manipulability is proposed in [40.49] using an event-based planner and a nonlinear feedback controller with the dynamic model of the robot.

As can be seen from the above literature, the issue of redundancy resolution in mobile manipulator has been often dealt with as an extension from the control of redundant systems but with the special case of non-holonomic constraints.

Uncertainty Due to Mobile Platform

Another main problem arising when controlling mobile manipulators, is the additional uncertainty due to the mobile platform. This is because the mobile platform in real world moves on the imperfect ground, which creates a large uncertainty on the manipulation although it can be negligible for navigation. Early work in the nineties studied how to control the manipulator when the base is under disturbance due to the ground condition in [40.50]. The disturbance was assumed to be unknown and considered as rotational motion only.

Also, model-based approaches are not always suited for the control of mobile manipulator because accurate models of mobile platforms are harder to obtain than models of manipulators. The extended Jacobian transpose algorithm is proposed in [40.51] for controlling the manipulator to overcome the excessive end-effector error or instability due to unmodeled vehicle dynamics. Similarly, since precise modeling of the interaction is difficult, decentralized control is proposed in [40.52]. It regards the interaction force from each system as unknown disturbance.

In [40.53], the control system is divided into mobile platform and manipulator, and two low-level controllers are used to control each system. The dynamic inter-

action force from the base is modeled as an unknown disturbance in manipulator control, and an adaptive controller was designed to deal with this disturbance. A redundancy resolution scheme avoids singularities. On the other hand, the effects of dynamic interactions between manipulator and wheeled base on the performance of the end-effector task are studied in [40.54].

In another aspect, there have been approaches without modeling interaction or dynamics of each system. A robust damping controller is proposed in [40.55] for the motion control subject to kinematic constraints but without any knowledge of dynamic parameters.

Neural network-based control also has been proposed in this respect. In [40.56], a neural network-based joint space control is developed for a mobile manipulator with unknown dynamic model and disturbance. Two neural network controllers are applied to manipulator and vehicle, respectively. The radial basis function network with weight adaptation is used in [40.57] for on-line estimation of nonlinear dynamics. The algorithm is applied to a simulation of a two-link manipulator on a mobile platform. Adaptive robust motion/force control has been developed for both holonomic and non-holonomic constrained mobile manipulators in [40.58]. It ensures stability and the boundedness of tracking errors in the presence of uncertainties in dynamic parameters and disturbances.

Sliding mode control and adaptive neural network control are combined together in [40.59]. Multilayered perceptrons are applied to estimate the dynamic model as one system, and the adaptive control is designed in the task space control. A sliding mode approach with neural network-based control is proposed in [40.60] for omnidirectional wheeled mobile manipulators.

Control Issues on Various Types of Mobile Platform

Although wheeled vehicles are one of the most general types of platform to provide mobility, there is an increasing tendency of using other types (Fig. 40.4).

Fig. 40.4 Mobile manipulators in various environments

Legged locomotion systems like humanoids and quadrupeds are becoming popular. The interesting new aspect of these systems is that the platform for locomotion can actively participate in manipulation. That is, the legs of the humanoid system can provide not only locomotion but also assist in manipulation. This is especially enabled by using the whole-body control framework [40.61–64]. This control framework considers the robotic system as a whole and utilize all the joints for both manipulation and locomotion. This is especially justified in legged robots because the mobile platform and manipulator use the same type of actuator. Other platforms use different types of actuation for base and manipulator.

Also, quadruped robots such as Robosimian from NASA JPL uses the leg parts to increase the workspace and dexterity of the manipulation. The legged system can provide more capability of manipulation than wheeled mobile platform because it can provide the full three-dimensional (3-D) motion of the base part such that the manipulation part can have much larger manipulation capability. The whole-body control framework is also applied to a quadrupedal robot in [40.65]. The robot does not yet have manipulator in this system, but the control framework can support the manipulation control if needed.

Mobile manipulators operating underwater are becoming more prevalent. The main difference to wheeled mobile platform is the effect of hydrodynamic forces during motion. An efficient dynamic simulation algorithm is developed for underwater mobile manipulator in [40.66], where various hydrodynamic forces can be modeled and incorporated. In [40.67], the hydrodynamic effect between the manipulator and vehicle is modeled and compensated. The demonstrated results improved performance in controlling both vehicle and manipulator. The underwater mobile manipulator is modeled using Kane's method in [40.68], which also incorporates the major hydrodynamic forces such as added mass, profile drag, fluid acceleration, and buoyancy.

Underwater mobile manipulators also have redundant degrees of freedom. In [40.69], redundancy created by the underwater vehicle is utilized to achieve secondary tasks, such as reducing energy consumption and maximizing dexterity, while executing the main task at the end-effector. A task-priority redundancy resolution technique is applied for this purpose. The restoring moment is minimized in [40.70] in redundancy resolution so that the performance of the coordinated motion control is improved.

Similar to other mobile platforms, the uncertainty due to the underwater vehicle is one of the major difficulties. To deal with this issue, an adaptive con-

trol approach is proposed in [40.71] that is robust in the presence of uncertainties in the vehicle and environment. An iterative learning algorithm is developed for the hydrodynamic effects in [40.72]. An adaptive tracking control is proposed in [40.73] that keeps the advantage of model-based control and has a modular structure. An observer-controller strategy deals with the difficulty of obtaining precise velocity measurements in [40.74]. This significantly improves the chattering of the output actuator caused by noise and quantization.

Aerial mobile manipulation has been actively investigated in recent years. Aerial mobile manipulation has different characteristics in another sense: stability and load capability. The dynamics of the manipulator or interactions with the environment can create stability problem in aerial mobile manipulation. Also, interaction forces and load are limited due to the capability of lift provided by the aerial platform.

An aerial mobile manipulator system with three 2-DOF arms is developed in [40.75]. The interaction between the manipulators and quadrotors is modeled so that the reaction forces and torques during flight and manipulation are compensated for stable flight.

A Cartesian impedance control is implemented in [40.76] and [40.77], while the task redundancy due to the added DOF from the aerial vehicle is used for secondary tasks in [40.76]. Hybrid force and motion control of tool operation in quadrotors are proposed in [40.78]. The dynamics of quadrotors are transformed into the tool-tip position and decomposed into the tangential and normal directions with respect to the contact surface. Then, a stabilizing controller is designed for the hybrid motion and force control.

40.2.3 Toward Control in Mobile Manipulation

Control of mobile manipulators is one of the most investigated topics since the beginning of the concept of mobile manipulation. Although the issues discussed so far in this chapter are still very important and need to be further investigated, interaction with humans and the environment is another important aspect to handle to enable mobile manipulators to come into our daily life. In this respect, force control at the end-effector of the mobile manipulator has been studied in [40.79, 80]. The issue of contact transition has been studied for non-holonomic mobile manipulators in [40.81]. A control strategy is proposed to deal with impulsive contact force on the mobile manipulator in [40.82].

On the other hand, the use of compliant actuators such as series elastic actuators (SEA) and variable stiffness actuators (VSAs) is expected to become more

popular. The topic of compliant actuators is covered extensively Chap. 21. The SEA has been developed for the purpose of safety and energy efficiency in the compromise of precise control. The VSA can overcome the disadvantage of SEA with additional actuation for changing stiffness.

Despite the complexity of implementing these actuators in terms of both hardware and algorithms, they are expected to be used more because there is an increasing need for safe robot–human or robot–environment interaction. The application of compliant actuators to mobile

manipulators would provide new challenges to the control issues of dealing with uncertainty and stability in addition to the precision of the manipulator itself. The compliance on the joints will provide larger uncertainty in the manipulator. This uncertainty affects not only the control of the manipulator but also the control of the mobile platform. The effect on the mobile base will be the stability problem in addition to the precision in control. Nevertheless, the introduction of soft/compliant actuators will be one of the important future directions to enable safe interaction in mobile manipulation.

40.3 Motion Generation

Methods to generate the motion of robots are fundamental to robotics. They are treated extensively in this Handbook (Chaps. 7, 8 as well as the entire Part E). As in the previous sections of this chapter, we will consider the state of the art in motion generation in the context of mobile manipulation. We will identify aspects of motion in mobile manipulation currently not fully addressed and will speculate about how these gaps might be closed.

In the context of mobile manipulation, the generation of robot motion poses a number of challenges, related to those laid out in the introduction to this chapter. Robotic systems able to perform a variety of tasks must possess versatile motion capabilities. This is usually realized through a large number of degrees of freedom, leading to high-dimensional motion generation problems. The humanoid robot Justin, for example, possesses 58 DOFs; the latest version of the Honda ASIMO has 57 DOFs. In addition to the high dimensionality of the associated configuration spaces, uncertainty represents a major challenges when generating robot motion. For applications in mobile manipulation, one simply cannot assume that a precise and complete world model is available at all times. The generation of motion therefore must consider the uncertainties present in the robot's world model. Furthermore, it is unrealistic to assume that the entire world will be perceivable all at once. This implies that the robot's world model will always be partial and potentially wrong in important ways. All this is compounded by the fact that the robots sensors and actuators themselves are prone to uncertainty. It is therefore apt to state that motion generation in mobile manipulation is subject to two of the problems we identified in the introduction: high dimensionality and uncertainty.

In this section, we will examine major branches of research in motion generation and analyze the degree

to which they are poised to address the challenges of motion generation in manipulation. But before that, of course, we must discuss what exactly these challenges are.

40.3.1 Problem Description

What are the requirements for robot motion in the context of mobile manipulation? Just as in the classical motion planning problem, a robot must be able to move from one place to another. This requires information about the spatial extent of objects and the resulting global connectivity of world. Algorithms that address this most basic requirement of robot motion are discussed extensively in Chap. 7.

In addition to global, goal-oriented motion, a mobile manipulator must also be able to maintain task constraints during motion: holding a glass of water upright, pointing a camera in an inspection task, or coordinating motion with another robot during cooperative manipulation. At the same time, it must be able to react quickly to unforeseen changes in the environment; global motion planning might not be fast enough and therefore has to be complemented by reactive obstacle avoidance.

While performing this task-consistent, global, and reactive motion, the safe and efficient movements of a mobile manipulator may also depend on kinematic, dynamic, or postural constraints. Postural constraints may be used to perform additional tasks or simply to move in the most energy economical posture to extend battery life.

Finally, all of the motion requirements (global, task-consistent, reactive, joint-limit avoiding, posture-optimizing) must be achieved and maintained in the presence of various sources of uncertainty. In mobile manipulation, there will always be uncertainty about the world model, which might be incomplete or partially

wrong; changes to the world model may happen without knowing the robot. And, of course, there is uncertainty in regards to sensing, affecting the robot's knowledge of its own state or the ability to predict the outcome of its actions.

As we will see, most existing areas of research in motion generation today cannot address all the aforementioned requirements at the same time. Furthermore, these motion requirements also necessitate sensing capabilities. It is therefore difficult to treat motion generation for mobile manipulation independently from sensing and perception.

40.3.2 Evaluation of the State of the Art

Sampling-based motion planning is the de facto standard for motion planning in robotics; the state of the art in that field is described in detail in appendix of Chap. 7. Here, we want to show some work that extends standard methods, such as probabilistic roadmaps (PRMs) and rapidly-exploring random trees (RRTs), to address some of the motion requirements of mobile manipulation.

Motion Planning

Motion planners have been devised to account for the changes in the configuration space when robots manipulate objects by picking and placing them, possibly handing them off to another robot in order to fulfill a motion task [40.83]. This enables complex sequences of repeated reach and grasps in very tight environments to achieve a planning objective.

Other planners enable the combination of global motion with task constraints [40.84, 85]. The resulting planners generate globally goal-directed motion while maintaining task constraints at the robot's end-effector. This enables collision-free motion while maintaining a fixed orientation of the end-effector, for example. This is realized by identifying lower dimensional, task-consistent manifolds in configuration space and confining possible motions to those manifolds. This is usually achieved through iterative optimization of sampled configurations, adding the computational complexity of global motion planning.

Planners are also able to devise global motion that is consistent with kinodynamic constraints and with actuation limits of robotic platforms. Kinodynamic planning addresses, for example, constraints imposed by nonholonomicity or by the dynamics of the robot [40.86]. Actuation limits become important when a robot is unable to lift a heavy load with its arm fully extended. In such a situation, a planner can generate a motion to slide the object closer to a region of the workspace where the mechanical advantage of

the robot kinematics enables the desired motion objective [40.87].

Global motion planning is computationally expensive. Therefore, it generally cannot operate at reactive rates. As a result, they are unable to satisfy the motion requirement of reactive obstacle avoidance. Of course, ideally one would determine a global motion plan at high frequencies; then planners would be able to satisfy global and reactive motion requirements. To overcome the provable computational complexity of planning, one has to resort to approximation algorithms. In other words, one has to trade completeness for computational efficiency. While there are probably many ways of accomplishing this, which may be the subject of future research, one possibility presented in the literature is the balancing of exploration and exploitation [40.88]. By replacing the exploration of motion planners with exploitation on those areas of configuration space where helpful information is available, it is possible to speed up planning by more than one order of magnitude.

Common to all of the motion planning approaches in this section is that they ignore uncertainty. They assume a perfect geometric world model and perfect execution capabilities. These assumptions generally do not hold in mobile manipulation. Hence, it will be difficult to extend traditional motion planning approaches so as to address the entire spectrum of motion requirements described above.

Further information regarding motion generation for mobile manipulation, in particular in the context of humanoid robots, has been collected in a special volume [40.89].

Feedback Motion Planning

Feedback motion planning [40.86, 90] addresses a particular type of uncertainty: actuation uncertainty. With this type of uncertainty, the robot might end up in a different state than it intended. An appropriate plan must therefore contain the correct action to take in every possible configuration the robot might end up in. Such a plan is called a navigation function. Given such a navigation function, the robot can perform Markovian gradient descent until the goal is reached.

Feedback motion planning also assumes a perfect knowledge of the world. The ability to address actuation uncertainty comes at a significant computational cost. Instead of having to compute a single path, an implicit representation of *all* paths has to be determined.

Trajectory Modification

There is an appealing complementarity between motion planning and control methods. While the former are good at addressing global motion constraints, the latter excel at reactive behavior, including obstacle avoid-

ance, force control, maintaining task constraints, etc. If the advantages of these two approaches could be combined, one would have made significant progress toward motion generation for mobile manipulation.

The simplest way of achieving this objective is through consecutive invocation: first determine a path consistent with global motion requirements, then apply control methods to the entire path to continuously optimize in response to changes in the environment or task constraints. This latter part, applying control to an entire path or trajectory as opposed to a single robot configuration, is called incremental trajectory modification.

All methods in this category perform optimization of a function, encoding various desirable properties of the trajectory, through some kind of gradient descent. The earliest method, called elastic bands [40.91], applies repulsive forces from obstacles and attractive internal forces to a discretization of the configuration space trajectory, leading to a behavior reminiscent of elastic material. This method was extended in the elastic strip framework [40.92] by applying these forces directly in the workspace to a discretization of the volume swept by the robot along its configuration space trajectory. Approaching obstacles deform the trajectory; when obstacles recede, the trajectory is shortened by the internal forces.

In contrast to the local reaction forces computed by the elastic band and elastic strip approaches, other approaches optimize trajectories globally in accordance with various criteria of optimality. This optimization problem can be cast as approximate probabilistic inference [40.93], then using message passing algorithms to find the maximum likelihood trajectory for a given objective. Alternatively, the optimization problem can be solved using the Hamiltonian Monte Carlo algorithm [40.94], where covariant functional gradient descent techniques perform local optimization. A stochastic variation of this method seems to be able to deal better with local minima [40.95].

Even though trajectory modification methods are often times labeled as motion planning methods, they do not perform global planning. They have been shown to work well in many realistic scenarios but can fail when gradient information is insufficient to find a solution. As a result, trajectory modification can serve as a powerful component for motion generation, but they cannot address all requirements of motion generation in mobile manipulation.

Integrating Planning and Control

Traditionally, global motion planners produce paths or trajectories that then get passed to the robot for execution. At execution time, these trajectories can be modified, for example, by the methods described in the

previous section. It is striking, however, that a planner determines an entire trajectory from start to goal, knowing well that in dynamic environments most of the trajectory will be invalidated within seconds due to the motion of obstacles.

To fully leverage the complementarity of global planning and control mentioned in the previous section, it might be necessary to shift the boundary between these two fields. This would imply that, instead of computing a detailed trajectory, global motion planning would only provide as much information as is required to avoid local minima during control. This leads to the idea of sequencing local controllers, which can be visualized as funnels, in such a way that a global motion task can be achieved [40.96]. Referring to Fig. 40.5, each controller can be viewed as a local plan for region of the configuration space (in the image, the configuration space is the imagined plane above which the funnels are arranged). Each funnel has an exit (the converged state of the controller) that leads into the opening of the next funnel. Arrangements of these funnels represent robust motion plans as each funnel (controller) inherently rejects uncertainty.

Such a shift of the boundary between planning and control is realized in the Elastic Roadmap approach [40.97]. It combines global planning with trajectory modification to yield an approach to motion generation capable of generating global, task-consistent, reactive, and constraint-respecting motion. It does so, however, by deliberately trading completeness for computational efficiency. While this approach works well in practices, no performance guarantees can be made. Also, this approach is not able to address uncertainty; it still assumes that the world and its changes are perfectly known.

Reasoning About Uncertainty

Partially observable Markov decision processes (POMDP) are a general framework to formalize

Fig. 40.5 Representing a motion plan as a sequence of funnels

problems involving actions that perform uncertain transition (uncertain outcome) between uncertain (not fully known) states (Chap. 15). POMDPs are so general that they can easily characterize the type of motion planning problem occurring in mobile manipulation. A downside of their generality and expressive power is the computational complexity of finding an exact solution, which is often intractable. To overcome this problem, one must resort to approximations.

Point-based POMDP solvers [40.98] provide such an effective approximation for the case that there is an uncertainty about the robot's state. The key idea of point-based solvers is to sample only parts of the solution space, avoiding regions unlikely to contain a solution [40.99]. Effectively, these methods exploit additional knowledge about the specific problem to guide the search for a solution.

In the context of motion generation, the roadmaps generated by traditional sampling-based motion planners can provide such knowledge for finding solutions to a specific motion planning problem [40.100, 101] or to any motion planning query in a given environment [40.4].

Considering uncertainty not only for the robot's state but also about the world model makes the problem even more difficult. Here also, it becomes necessary to approximate the state space of the world, leading to discrete approximations of the corresponding state space [40.102, 103].

While all the methods mentioned so far successfully address uncertainty, their computational complexity prevents them from being reactive. This means that all initial assumptions about the world, including assumptions about uncertainty distributions (encoded in the POMDP), must be correct and remain correct throughout the entire motion. In the context of mobile manipulation, it is difficult to think that even the initial assumptions could be correct.

If one does not want to rely on fixed assumptions about uncertainty, for example in the state transition function, one has to rely on sensing. For example, a robot might be able to reduce the uncertainty about its own state sufficiently well to be able to avoid reasoning about this type of uncertainty. But this in itself is a very strong assumption. By making such strong assumptions, it is possible to reduce the complexity of addressing uncertainty in a meaningful way, leading to a polynomial time to address uncertainty in the context of mobile manipulation [40.104]. While this approach achieves reactivity, task consistency, and is able

to address other constraints, it is incomplete and no performance guarantees exist.

40.3.3 Toward Motion Generation for Mobile Manipulation

The literature contains a number of powerful technical tools and conceptual approaches that have proven effective in the context of motion generation: sampling-based motion planners, planning for feedback, optimization for incremental trajectory modification, sequencing of controllers, shifting the boundary between planning and control, and approximative solutions to POMDP-based formalization of motion planning problems. The use of assumptions to improve the computational efficiency is inherent to all of them – no surprise, given that even simple motion planning problems are already PSPACE-complete.

For each of the aforementioned motion requirements in mobile manipulation, when considered in isolation, an adequate solution exists. But no method or approach addresses all of them in coherent fashion with characterizable performance. Nevertheless, in practice, motion generation capabilities exist for many interesting applications in mobile manipulation.

With respect to the goals laid out in the introduction to this chapter, this discussion has exposed, however, that all approaches still depend on detailed prior knowledge about the environment. Most of this prior knowledge is difficult to obtain in the context of mobile manipulation. For example, accurate geometric models of the environment are unlikely to be obtainable at a global scale. And even if they were attainable, they will likely be outdated very quickly and would require constant updating. It might be even more difficult to obtain adequate characterizations of uncertainty for arbitrary motion problems.

In response to these difficulties, it is highly likely that the close integration of real-world sensing into motion generation will become a more active area of research. This sensing must be used to alleviate the needs for prior world models. This development might parallel the *shifting the boundary* between planning and control, only this time between planning and sensing. Instead of performing planning on very detailed and all encompassing world models, it might be more practical to plan in a coarse and approximate world world, leaving it to perception to fill in the details as they become relevant.

40.4 Learning

We mentioned high dimensionality, uncertainty, and variability as core challenges for robotic systems that leave prestructured lab environments. Learning is the core approach to cope with the variability of tasks a robot may need to perform in unstructured environments.

The topic of learning is orthogonal to all of the other topics discussed in this section: Learning methods are successfully applied to grasping and manipulation, mobility, control, motion generation, and perception. We will highlight representative approaches in these areas below, but first we want to discuss in more general terms the relation between the areas of machine learning and robotics.

A core question is whether existing machine learning methods can without need for modification be applied in robotic domains. Or whether genuinely novel issues are raised in the context of robot learning that necessarily go beyond core machine learning research. This is fundamentally related to the question *Is there a generic prior?*

In the Bayesian view, learning means computing the posterior

$$P(M|D) = \frac{P(D|M)P(M)}{P(D)}. \quad (40.1)$$

A similar discussion could refer to the choice of hypothesis space and regularization. But for simplicity we take the Bayesian view as a reference. The machine-learning community has made great progress in two respects: First, it developed a rapidly growing set of general and fundamental modeling tools to formalize learning problems, including standard parametric and nonparametric models, graphical models, infinite (hierarchical Dirichlet process) models, models combining probabilities with first-order logic, random set models, etc.

Second, the community has developed a large set of methods to solve learning problems, i. e., compute the posterior or optimize discriminative models, including a wide range of probabilistic inference methods and leveraging the tight relations to the field of (constrained) optimization.

With this range of modeling formalisms and computational methods available, what problems are left? Interestingly, a core issue remains the concrete specification of the prior $P(M)$ or hypothesis space itself. An example is the current research on deep representations: *Weston et al.* [40.105], for instance, argue that deep learning can concisely be understood as a form of regularization of intermediate representations, includ-

ing auto-encoders as special case but generalizing it to arbitrary choices of embeddings. Such a regularization is one-to-one with the choice of model prior in the Bayesian formulation of learning methods. The large majority of (non-deep) regression and classification models are linear in some features (we include Hilbert space features here). The regularization is typically generic: L_2 or L_1 on the respective parameters. Therefore, the model prior is primarily determined by the choice of features.

Researchers generally agree that a core challenge of machine learning is in the specification of the prior $P(M)$ – respectively the choice of features [40.106, 107]. However, is the question about the *right* prior a genuine machine learning question? In other terms: Does there exist a *generic* prior that might perform well in any domain, or is a good choice of prior inherently domain specific, requiring expert knowledge?

Related to this question is the idea of *learning the prior* – or learning the right features. Of course, in the strict sense, a prior must not be data based. When discussing the learning of features, people usually presume a hyperprior that implies a class of potential features. However, it is questionable whether there exist generic hyperpriors over feature classes that would allow systems to learn arbitrary features suited in any domain. Some aspects of priors seem generic and are discussed extensively within machine learning: L_1 or L_2 regularization to enforce sparsity and penalize complexity; metric or topological embedding to enforce the preservation of information in internal (deep) representations. However, the structural complexity of suitable features in real-world domains seems – in the eyes of a roboticist – beyond such generic properties.

In this light, it is not surprising that the success of learning methods within robotics often relies on an insightful way to model the problem using machine learning formalisms combined with a good choice of features. Both depends on the roboticist's expert knowledge and his understanding of appropriate priors in real world domains, contrasting the idea that generic machine learning and priors could be applied for learning in robotic manipulation.

40.4.1 Problem Description

Perhaps a reason for the great success of machine learning is that its problems are – in contrast to robotics – rather straightforward to define rigorously. In most cases a learning problem is defined in terms of minimizing a loss or risk (often approximated using cross

validation), computing a posterior, or maximizing an expected return. Feature and hyperparameter selection are subsumed in these objectives.

To make this more concrete, we choose to detail one specific machine learning approach: conditional random fields (CRF) [40.108]. CRFs have become a default starting point for addressing many learning problems, especially in robotics. And CRFs are a very general way of modeling problems, as we discuss briefly in the following, and should therefore be a standard tool for roboticists.

A CRF could also be named a *conditional graphical model* or *conditional factor graph*. It describes a structured probability distribution over labels y where the factors that define this distribution additionally depend on some input x . The following summarizes the essentials of CRFs:

- We consider output variables $y = (y_1, \dots, y_l)$ and input variables x . A CRF is defined by a joint function over x and y of the form

$$f(x, y) = \sum_{j=1}^k \phi_j(x, y_{\partial j}) \beta_j = \phi(x, y)^T \beta, \quad (40.2)$$

which describes the predicted output as

$$y^*(x) = \operatorname{argmax}_y f(x, y). \quad (40.3)$$

Each feature $\phi_j(x, y_{\partial j})$ depends on a subset $y_{\partial j}$ of output variables, $\partial j \subseteq \{1, \dots, l\}$. The function f is also called (neg-) *energy* or *discriminative function*. CRFs can be trained based on a probabilistic interpretation or with a hinge loss.

- In the *probabilistic interpretation* [40.108], CRFs define a conditional probability distribution over y ,

$$p(y|x) = \frac{e^{f(x, y)}}{\sum_{y'} e^{f(x, y')}} = e^{f(x, y) - Z(x, \beta)} \quad (40.4)$$

$$= e^{-Z(x, \beta)} \prod_{j=1}^k e^{\phi_j(x, y_{\partial j}) \beta_j}, \quad (40.5)$$

which is a Boltzmann distribution of f with log-partition function

$$Z(x, \beta) = \log \sum_{y'} e^{f(x, y')}$$

ensuring the conditional normalization. This is trained by minimizing

$$\beta^* = \operatorname{argmin}_{\beta} L(D, \beta) + \lambda \|\beta\|, \quad (40.6)$$

where the second term is an L_2 (Ridge) or L_1 (Lasso) regularization and the first the neg-log-likelihood on data $D = \{(x_i, y_i)\}_{i=1}^N$. The optimum is found using a Newton method, using the following gradient and Hessian terms:

$$\begin{aligned} L(D, \beta) &= - \sum_i \log p(y_i | x_i) \\ &= - \sum_i [\phi(x, y_i)^T \beta - Z(x_i, \beta)], \end{aligned} \quad (40.7)$$

$$\nabla_{\beta} Z(x, \beta) = \sum_y p(y|x) \phi(x, y), \quad (40.8)$$

$$\begin{aligned} \nabla_{\beta}^2 Z(x, \beta) &= \sum_y p(y|x) \phi(x, y) \phi(x, y)^T \\ &\quad - \nabla_{\beta} Z [\nabla_{\beta} Z]^T. \end{aligned} \quad (40.9)$$

Computing $p(y|x_i)$ (or the factor marginals $p(y_{\partial j}|x_i)$) for all x_i is analogous to the E-step of expectation maximization; the parameter update of β in each Newton iteration is analogous to the M-step. For arbitrary structures, the Hessian term $\sum_y p(y|x) \phi(x, y) \phi(x, y)^T$ may be infeasible to compute exactly. Still, Newton methods with approximate Hessian may be significantly faster than gradient-based methods.

- In the *discriminative interpretation* [40.109], the CRF is trained by minimizing a *hinge loss*

$$\begin{aligned} \min_{\beta, \xi} \quad & \beta^2 + C \sum_{i=1}^n \xi_i \\ \text{s.t.} \quad & \forall_{y \neq y_i} : f(x_i, y_i) - f(x_i, y) \geq 1 - \xi_i, \quad \xi_i \geq 1, \end{aligned} \quad (40.10)$$

using either perceptron or linear programming methods similar to how SVMs use them [40.109]. This approach is also called *structured output SVM*.

- *Kernelization* works for both types of training. Further, in the probabilistic interpretation, the ridge regularization can be replaced by a Gaussian prior $P(\beta) = \mathcal{N}(\beta | 0, \sigma^2/\lambda)$ and a fully Bayesian predictive posterior $P(y|x, D)$ can be computed (just as for Bayesian ridge regression and Gaussian processes).
- CRFs are a very general class of learning tool. We list *special cases*, where the options concern the special case input and output spaces, *probabilistic* or *hinge loss* training, *kernelization*, *bayesianization*, and of course the choice of features (explained below):
SVM = CRF(kernel, hinge, $y \in \{0, 1\}$, ϕ_C)
logistic regression = CRF(prob, $y \in \{0, 1\}$, ϕ_C)

Gaussian process (GP) = CRF(prob, bayes, kernel,
 $y \in \mathbb{R}, \phi_R$).

GP classification = CRF(prob, bayes, kernel,
 $y \in \{0, 1\}, \phi_C$)

factor graph (MRF) = CRF(prob, $x = \emptyset$)

hidden Markov model (HMM) = CRF(prob, $y =$
 $(y_1, \dots, y_T), \{\phi_t\}$)

ridge regression = CRF(prob, $y \in \mathbb{R}, \phi_R$)

The regression case is somewhat special, see below.

- We give three *feature examples* for the cases of multiclass classification, Markov chains (like HMMs), and the somewhat special case of regression.

For a three-class classification, one chooses

$$\phi_C(y, x) = \begin{pmatrix} [y = 1]\phi(x) \\ [y = 2]\phi(x) \\ [y = 3]\phi(x) \end{pmatrix} \in \mathbb{R}^{3k}$$

where $y \in \{1, 2, 3\}$, $[expr.] \in \{0, 1\}$ is the indicator function and $\phi(x) \in \mathbb{R}^k$ an arbitrary (e.g., polynomial) input feature vector. The effect of the indicators is that for each class, a different subset of β -elements define the function f .

For a Markov chain $y = (y_1, \dots, y_T)$ with binary y_t , one chooses

$$\phi_t(y_{t+1}, y_t, x) = \begin{pmatrix} [y_t = 0 \wedge y_{t+1} = 0] \\ [y_t = 0 \wedge y_{t+1} = 1] \\ [y_t = 1 \wedge y_{t+1} = 0] \\ [y_t = 1 \wedge y_{t+1} = 1] \\ [y_t = 1]\phi_t(x) \end{pmatrix} \in \mathbb{R}^{4+k},$$

where $\beta_{1:4}$ determines the transition probabilities, and $\beta_{5:5+k-1}$ plays the same role as in the logistic regression of y_t on input features $\phi_t(x) \in \mathbb{R}^k$. If $x = (x_1, \dots, x_T)$ is also a time series and if we choose input features $\phi_t(x) = \phi_t(x_t)$ to depend only on x_t , we are in the case of HMMs. The great strengths of Markov chain-CRFs over HMMs is that $\phi_t(x)$ may depend arbitrarily on the whole of x . In the (unusual) regression case, we may choose

$$\phi_R(y, x) = \begin{pmatrix} -\frac{1}{2}y^2/\sigma^2 \\ \phi(x)y/\sigma^2 \end{pmatrix} \in \mathbb{R}^{1+k},$$

which leads to $y^*(x) = \phi(x)^T \beta$ and $p(y|x) = \mathcal{N}(y | y^*(x), \sigma^2)$ with a partition function independent of x and β . Therefore, a single Newton step leads to the well-known optimal parameters of ridge regression. GPs are the bayesian kernel variant of this.

An extreme special case is logistic regression, where the graphical model only concerns a single binary output variable y , the distribution over which depends on the input x . On the other side, also any kind of standard (non-conditional) graphical model over y is an extreme special case of a CRF that lacks the dependence on any external x . Conditional Markov chains (e.g., in linguistics), Markov random fields (in computer vision), and many other models can be viewed as instances of CRFs.

Given this concrete framework of CRFs, the problem – from the robotics perspective – essentially becomes to propose an appropriate graphical model structure over y , and to choose appropriate features $\phi(x, y)$. Both choices together correspond to the choice of hypothesis space or prior as discussed above.

40.4.2 Evaluation of the State of the Art

Perhaps the best developed area for the application of learning methods in robotics is perception.

Learning for Perception and Scene Understanding

Saxena et al. developed a series of methods that very successfully employ the general framework of CRFs in various perception tasks. In [40.110] they train CRFs to predict the depth in two-dimensional (2-D) views; [40.111] learns CRFs to classify a *grasp*-affordance in the 2-D view; [40.112] learns CRFs (or SVMs) to classify the *place*-affordance of locations; [40.113] learns CRFs to label and thereby anticipate the actions and movements of demonstrators. These works are exemplary for the power of current machine-learning methods for perception – but also in that their success relies on the creative choice of problem formalization and features. As an example, we would like to mention the unique features chosen to be indicative of concavity and place stability to predict cup-like place locations in [40.111]. Could such types of features ever be discovered autonomously by more advanced machine learning methods?

Also, for 3-D point cloud data the definition of clever features turned out to be essential for basic regression and classification problems [40.114].

With respect to our discussion of learning features, in standard image classification tasks there has recently been great success in using generic (sparse coding) priors to learn features that significantly outperform hand-coded features (like robust features (SURF) and histograms of oriented features (HOG) [40.115]. Such learned features correspond to local 2-D or 3-D appearance patterns (which define the codebook); the histogram of such patterns turns out to be an excellent basis for image classification. It seems promising that

typical 2-D CRF approaches to classify affordances – as those mentioned above – can be extended to also use learned local features. However, there may be limitations to such generically learned features. For instance, naively they do not respect any natural invariances (such as affine or illumination invariance; this can be fixed by artificially incorporating such invariances in the dataset). Using merely sparse coding priors, they are unlikely to reflect stronger priors (e.g., Gestalt laws, or kinematic understanding of rigid body scenes) of natural physical environments. For instance, the concavity feature for placement prediction seems in strong contrast to such learned features.

As a conclusion with respect to perception, the existing machine learning machinery, including novel feature learning methods have shown great success. For specific mobile manipulation tasks (like affordance prediction) this often relied on well chosen problem formalization. As is the case also in the following topics, a core question for future research are novel ideas for feature classes and priors, that are generic and support the learning of features for manipulation tasks, but incorporate stronger physical world priors than existing approaches.

Learning for Grasping

The ability to grasp is essential to manipulation and approaches to learning to grasp therefore deserves special attention. Learning to grasp has been addressed from at least two perspectives.

First, on the perceptual side, several authors have proposed methods to directly classify 2-D or 3-D appearance patterns that predict a grasp affordance [40.111]. On the positive side, this implies a very close perception–action cycle; the percept is directly translated to a potential pregrasp location without need to estimate a 3-D shape of the object or even a notion of objects and shapes. Such approaches provide a sort of heat map of potential affordances, e.g., for exploration or to reduce the number of options for manipulation. But they lack the generality of grasp approaches that take into account the goal of applying a certain force or motion to an object – but classically require a shape estimate.

Second, concerning the grasp motion itself, a basic approach is to employ policy search methods to improve a parametric dynamic movement primitive (DMP) model of the grasp motion [40.116].

Learning for Motion Generation

There exists extensive work on learning methods for control, e.g., in the form of system identification, (model-based and model-free) reinforcement learning and learning from demonstration. It is beyond the scope

of this chapter to cover this. Instead, here we focus on learning in the context of path finding or trajectory planning for manipulation.

A core issue of motion generation for manipulation is the question of the right task space. For instance, the work by *Cakmak* and *Thomaz* on learning from human interaction [40.117] suggests that the question of what is the actual task space should be in the center of communication. In a certain formalization, the choice of the task space of a motion is perfectly analogous to the choice of features in machine learning: The mapping from a geometric problem setting to an appropriate motion can be formalized as a CRF [40.118], where the optimal motion maximizes a discriminative function (or neg-cost function). Typically such a cost function is a sum of squares of features, where each feature captures some error in some nonlinear task space. The problem of finding appropriate task spaces – the right features of motion – is therefore analogous to the problem of finding appropriate features in machine learning. And as for generic machine learning, the core questions are: what is a general class of potential features (of potential task spaces), and what is a possible prior over this class.

Jetchev and *Toussaint*'s task space retrieval (TRIC) approach [40.119] considers a combinatorial set of potential task dimensions that refer to various absolute and relative coordinates of objects and uses a Lasso prior to select those features that best explain a set of demonstrated trajectories. While this successfully extracts the ground-truth task spaces w.r.t. which the given trajectories have been optimized, the approach still seems limited by the crude set of allowed features. Relative coordinates (w.r.t. object centers) cannot express more meaningful and better generalizing concepts, e.g., fitting one piece into another. Further, features of manipulation motions might refer to the temporary interaction with contacts or other environmental constraints [40.120, 121]. It should be the subject of future research how such aspects could span a well-formalized set of features that leads to an appropriate prior over manipulation motions and respective optimization methods.

The above discussion views motion as being modeled by a cost (or discriminative) function. This is close to the view of motion as being modeled by an attractor (Lyapunov or potential) function; a cost function implies such a potential in the form of the cost-to-go function, and shifting the modeling directly to the cost-to-go function avoids the optimization step. The core issue of finding the right features for modeling the potential remains unchanged. TRIC [40.119] in fact models on the level of the cost-to-go instead of the cost function.

However, these views on modeling motion seem orthogonal to sample-based path finding approaches, as they traditionally operate only in configuration space and employ a discrete notion of feasible/infeasible and goal region.

Learning Sequential Manipulation from Demonstration

It is fairly recent that learning has also been applied on the level of higher level sequential manipulation. *Niekum et al.* [40.122] present a complete system to analyze a demonstrated sequential manipulation and *re-play* it in a robust way on a robot, including its ability to search for alternative steps if some manipulation failed. Again, the choice of representation is the heart of this method: in [40.122] skill trees are used to represent the learned policy. *Alexandrova et al.* [40.123] extend such approaches by proposing an explicit user interface that allows the demonstrator to correct the robot's interpretation of the task and e.g., explicitly communicate the relevant task spaces.

Learning sequential manipulation is structurally one of the most interesting research challenges as it eventually requires choices of representations and priors on all levels, from perception and motion generation to the higher level representation of action and cooperation policies. The abovementioned work does first steps in the context of learning from demonstration. But much research needs to be done to enable robots to autonomously acquire skills that would allow them to control and manipulate the state of their environment as dexterously as we humans do.

40.5 Perception

The need for perception is one of the main culprits in making problems in manipulation high dimensional. Technological as well as biological agents possess many sensors to perceive their environment. Humans, for example, possess on the order of 300 million nerve endings that produce a rich, continuous stream of information about the world, which is preprocessed and ultimately routed to the brain. The same is true in mobile manipulation: it is not uncommon for robots to be equipped with several cameras, each having millions of pixels, and each contributing to the high dimensionality of the input space.

To illustrate this point: A simple, black and white (not gray scale!) camera with only one thousand pixels can sense many, many more distinct images (namely, $2^{1000} \approx 10^{310}$) than there are atoms in the observable universe (about 10^{80}) or than nanoseconds have elapsed since the big bang (about 4.354×10^{26}). Even if ev-

40.4.3 Toward Learning in Mobile Manipulation

We above raised the question whether existing machine learning methods can without need for modification be applied in robotic domains, or whether genuinely novel issues are raised in the context of robot learning that necessarily go beyond core machine learning research. The above examples give two answers to this: First, standard machine learning tools like **CRFs** are widely and very successfully applied within the area mobile manipulation, employing off-the-shelf algorithms for training. Second, however, the above examples all show that the actual crux is in the modeling of the learning problem itself, in particular in the choice of features, the used regularization and the chosen structure of the output. These are issues that require substantial domain expertise. In some cases, modern approaches to feature learning or feature selection are indeed successful – particularly impressive are novel sparse coding principles to train perceptual features [40.115]. However, in many cases successful learning for mobile manipulation requires that a very specific feature space has been chosen based on the roboticist's insight (e.g., the potential operational spaces in **TRIC**, or the shape concavity feature to predict placement).

If we had a more fundamental theory of real-world mobile manipulation problems, we could hope that such a theory would also inform us on what are promising and general feature spaces and priors for learning in manipulation.

ery atom in the universe would generate one such image every nanosecond, all possible images would not have been generated by the time the universe dies its postulated heat death in 10^{100} years. Biological agents can cope with this high dimensionality, of course, because there is substantial structure in the world, i.e., many of the possible images simply do not occur in nature or some of the variability in the data is not relevant for the task at hand and can be ignored.

In this section, we will survey different successful approaches to perception for mobile manipulation that leverage this structure in perceptual data. We will mostly focus on visual perception, reflecting the emphasis of ongoing research activities. The foundations of perception in robotics are presented in great detail in Part C of this Handbook. Chapter 42 also contains relevant approaches to perception.

40.5.1 Problem Description

Perception is the process of interpreting sensory data to enable useful actions. In the context of robotics, this may be – given the state of the art – the most suitable, albeit very broad definition of the perception problem. It differs appropriately from the definition most commonly used in psychology in that the goal of perception is not solely to gain an understanding of the world, but also to use such an understanding to enable task-directed actions. This modification in fact can be seen as a simplification of the original perception problem, as only those aspects of the environment must be perceived that are relevant to a particular action. And, in fact, there is evidence from the human perceptual system that such a limitation does indeed take place, and sometimes leads to odd perceptual deficiencies [40.124].

In the context of robotics, the earliest perception work followed the psychologists' definition of perception. It focused on the use of visual perception to derive an exact 3-D model of the thing being perceived from its two-dimensional optical projection onto a camera sensor [40.125]. However, this problem is mathematically ill-posed (three-dimensional shape information cannot be reconstructed unambiguously from its two-dimensional projection) and, as we argued above, also high dimensional. To enable robust and competent perception in the context of mobile manipulation, it therefore seems sensible to attempt to reduce the complexity of perception, lending further support to our definition of perception above.

40.5.2 Evaluation of the State of the Art

Much of the work we will discuss in the remainder of this section follows the robotics-specific view of the perception problem given above. However, we will start out by surveying impressive advances made toward the objective of reconstructing three-dimensional, geometric models of the environment. Only the future can tell us if these methods are well suited to supporting the kind of complex and general manipulation tasks encountered in mobile manipulation. In the subsequent sections, we will then cover alternative approaches.

3-D Mapping and Localization

Recently, there has been remarkable progress in dense 3-D mapping and visual SLAM. What originated with DTAM [40.126] lead to current systems like LSD-SLAM [40.127] which efficiently and rather robustly estimates a 3-D environment model in real-time, without GPU, from monocular video.

Efficient Dense and Multiresolution Mapping

Recent multiscale surfel models [40.128, 129] using RGB-D sensors are an alternative to directly pixel-based reconstruction methods and provide a similarly dense 3-D model. In [40.130] and [40.131], a 3-D representation, Octree, is proposed having multiple resolutions based on a probabilistic approach. This 3-D multiresolution method can provide flexible occupancy mapping depending on the demand of the high or low resolutions. Saarinen et al. [40.132] proposed normal distributions transform occupancy map (NDT-OM), which has the compactness from NDT maps and the robustness from occupancy maps. This algorithm supports for multiresolution maps and it efficiently enables mapping in dynamic environments.

These developments imply that, leaving system integration problems aside, we may today assume to have access to precise 3-D mesh models of the environment. In the concrete mobile manipulation context 3-D information is needed with high resolution only when the robot is near the object or the environment. Therefore, practical techniques for multiresolution map are developed based on the distance from the robot. Droschel et al. [40.133, 134] show 3-D multiresolution maps where sparse resolution is used for the environment far away and high resolution is used for the object to be interacted soon.

Mapping and Tracking with Moving Objects

Most methods for 3-D mesh estimation assume a static environment (but moving sensor). The segmentation into objects and dealing with moving objects – or rather exploiting the movement of objects – is left aside. However, fortunately recent approaches adopt a more integrated view on perception by jointly addressing the problems of dense 3-D reconstruction, moving object segmentation and tracking, and kinematic joint perception [40.135, 136], similarly as has previously been done on the basis of key points. We think that such integrated perception systems, fusing visual evidences and priors on multiple levels of representations (from low-level dense pixels to high-level rigid body hypotheses) should be the core effort of future research in this area.

Other approaches deal with general dynamic environments by efficiently updating the map continuously. Especially, in the real world problem, there are always moving obstacles and the environment itself can change over time. A incremental update algorithm is proposed in [40.137] for grid-based spatial representations for dynamic environment due to moving obstacles. Distance maps, Voronoi diagrams, and configuration-space collision maps are updated with the algorithm for the changes in the environment. In [40.138], velocity

occupancy space is proposed by adding the velocity obstacle concept into occupancy grid. This is to enable the robot to efficiently navigate through uncertain moving obstacles.

Indoor/Outdoor

Finally, the usage of a map can be different for indoor or outdoor applications. The outdoor map is mainly used for navigation whereas the indoor map is for both navigation and manipulation. The map for outdoor or field applications needs to cover wider range of area for navigation and the mobile platforms do not require high resolution maps compared to indoor applications. Indoor applications, however, typically require higher resolution even for navigation because there are more obstacles and less free space. Because of this space restriction, the navigation route needs to be planned carefully considering the obstacles. Manipulation tasks are more involved in the indoor applications such as cleaning, connecting hoses, and locking a valve, which tasks must require much higher resolution than typical navigation tasks.

For such different applications, the maps for indoor and outdoor can be quite different. Thus, in [40.139] pictures are used for the classification of the current environment. Specifically, Hue color component and color temperature values from each image are used with k-nearest neighbor (KNN) classifier to classify the environment into indoor or outdoor. *Payne and Singh* [40.140] proposed a simple system for the indoor-outdoor classification, which can be used as a real-time system. It is based on the assumption that indoor images contain more straight lines than outdoor environments.

Differently from indoors, the outdoor map often requires terrain information. In [40.141], the system classifies if the current environment is indoor or outdoor, then terrain mapping is used for outdoor environment. It also provides seamless integration of mapping between indoor and outdoor environment.

Active and Interactive Perception

The success of the 3-D mapping approaches presented in the previous section is enabled by camera motion. This motion provides a continuous stream of incrementally changing two-dimensional projections of the three-dimensional scene. This enriched perceptual information helps resolve the ambiguities of the projection from 3-D to 2-D, thus overcoming limitations of static vision approaches.

Perceptual algorithms that deliberately change the sensor to optimize the perceptual processes are called *active*. Among active perception methods, active vision is probably the most prominent one [40.142–144]. But

active haptic perception methods also hold promise as a perceptual approach for mobile manipulation. Active haptic perception has been used for object localization [40.145, 146], contact point localization [40.147], and for estimating the object's shape [40.148].

The concept of active perception can be extended to include interactions with the environment. Now the observer is able to manipulate the environment to reveal additional perceptual information, either by removing obstructions or by creating sensory signals that would otherwise not be observable. The class of perceptual algorithms relying on motion of the sensor as well as the deliberate application of forces to the environment is referred to as *interactive perception*.

Interactive perception eliminates the traditional boundary between perception and manipulation, combining both into a tightly coupled feedback loop. Manipulation now becomes an integral part of perception – in addition to being an objective in itself. At the same time, perception of task-relevant information is now critically enabled by manipulation. This combined perception-and-manipulation process links inseparably the goals of achieving a manipulation task and of acquiring perceptual information. These two goals must be balanced appropriately, as it is not desirable to perceive the world without progress toward the task, and it most often is not possible to achieve the task without perceiving something about the world first. Now, in addition to perception and manipulation, we must also consider aspects of machine learning: how do we balance progress toward the task (exploitation) with the goal of acquiring sufficient information to reach the goal robustly and reliably (exploration)? These and many related questions are current topics of research in this emerging field at the intersection of perception, manipulation, and machine learning.

Using interactive perception (or perceptual manipulation, if one prefers), it is possible to separate piles of objects so that they can be perceived, manipulated, and sorted [40.149–151]. It is also possible to interactively search for objects by removing obstructions [40.152]. Using interactive perception, it becomes possible to reveal sensory information about the articulations of objects in the environment, i. e., about their inherent degrees of freedom [40.153]. This ability is a perceptual prerequisite for mobile manipulation, as the degrees of freedom of an object are generally linked to its function. For example, by pushing on a door handle and observing its motion, it is possible to perceive the revolute joint connecting the handle to the door. Operating this revolute joint is necessary to open the door.

Interactive perception approaches based purely on vision data exist for planar objects [40.154] and three-

dimensional articulated objects [40.155, 156]. Their performance can be improved significantly by relying on RGB-D data [40.157, 158]. Interactive perception methods have been integrated with object databases so as to recognize previously seen objects and the associated kinematic model [40.159]. Online interactive perception enables the integration of interactive perception directly into the manipulation process [40.153]. This permits to detect failures, monitor progress, and identify the successful completion of a manipulation action. It is also possible to categorize novel types of articulation with interactive perception [40.160, 161]. Interactive perception can include additional modalities, such as proprioception and audition, for example, to identify objects [40.162].

One of the challenges remains the selection of appropriate actions for interactive perception. There are many possible ways to interact with the environment but only few of them will reveal relevant information. The selection of promising actions can be learned from experience [40.163] or by entropy-driven exploration [40.164]. The information obtained from such exploration can be represented in relational knowledge about the world [40.165].

The work discussed above has demonstrated that interactive perception is a promising approach to perception *and* manipulation in the context of mobile manipulation. It has resulted in robust perception that relies on few assumptions about the world, and in particular does not rely on the existence of prior geometric models. It also has resulted in robust manipulation, supported by the most task-relevant perceptual feedback. Interactive perception eliminates the boundaries between perception, action, and learning. While this seems like a complication, the close integration of these different aspects of robot behavior lead to novel solutions of long-standing challenges in perception and manipulation.

Affordance Detection

An affordance can be viewed as an opportunity of an agent to perform an action in its environment. The term dates back to 1977, when it was introduced by psychologist *Gibson* [40.166]. Since then the term has been used inconsistently with slight variations of meaning [40.167].

Here, we regard an affordance as an opportunity to instantiate a behavioral capability of the agent. Such an instantiation of a pushing action, for example, selects the objects involved (the robot's hand and a door han-

dle within reach) and determines other free parameters of the behavior (pushing down on one side of the door handle).

It is appealing to focus perception of affordances as, by definition, this will focus perception only on those aspects of the environment that must be known to instantiate and successfully execute a certain behavior.

Research on affordance perception is intimately linked with research on affordance learning [40.168–170]. A modern view perspective is to consider affordance learning for manipulation as a statistical relational learning problem [40.171].

More low-level affordance perception research considers the problem of labeling scene segments by their affordance of certain actions, often using conditional random fields (CRFs) to train the labeled segmentation. This has extensively been addressed in the case of learning to detected grasp affordances [40.172–175].

40.5.3 Toward Robust Perception

Perception is one of the great challenges in mobile manipulation. We recall that the objective of mobile manipulation research is to a) maximize task generality of autonomous robotic systems, while at the same time b) minimizing the dependence on task-specific, hard-coded, or narrowly-relevant information. Given these objectives, it becomes clear that the complex and diverse information required for task generally must be acquired through perception. And perception must also compensate for the envisaged reduction of a priori knowledge available to the agent. Perception plays a central role in realizing mobile manipulation.

In this section, we surveyed some approaches designed to meet the challenges posed by the perception requirements of mobile manipulation. While a multitude of promising approaches exist, today there is no generally accepted framework or philosophy for machine perception. Evidence from human perception may suggest that such a common framework exists. Some results seem to imply that there are some shared working principles between vision and audition [40.3]. Irrespective of this, there is strong evidence that human perception is built to support action. This becomes apparent already in the retina, which is far from being a general sense organ; it contains highly specialized circuitry tailored for task-relevance [40.176]. Maybe this too can be a clue for how to address perception in robotics: Maybe we need much better low-level features?

40.6 Conclusions and Further Reading

While mobile manipulation requires the integration of methodologies from almost all aspects of robotics – we mentioned grasping, control, motion generation, learning and perception – it also suggests alternative approaches to the state of the art in these areas of research. Instead of considering each research area as independent, research in mobile manipulation exploits their interdependence when this simplifies the overall problem. Active and interactive perception, i.e., combining manipulation and 3-D perception, is one example that departs from the goals of the individual subareas: (1) general 3-D reconstruction from passive data and (2) manipulation planning

given a 3-D environment model. Instead, these approaches view both as an integrated and potentially simpler problem.

In the present survey we only briefly covered the various aspects and their interdependencies. Which of the approaches will turn out to be the most successful for the integrated overall goal of mobile manipulation is an ongoing debate. An interesting starting point for further reading are the various workshops that focus on the integrated nature of mobile manipulation and robotics as a whole. A list of these workshops is maintained on the Website of the Technical Committee on Mobile Manipulation.

41. Active Manipulation for Perception

Anna Petrovskaya, Kaijen Hsiao

This chapter covers perceptual methods in which manipulation is an integral part of perception. These methods face special challenges due to data sparsity and high costs of sensing actions. However, they can also succeed where other perceptual methods fail, for example, in poor-visibility conditions or for learning the physical properties of a scene.

The chapter focuses on specialized methods that have been developed for object localization, inference, planning, recognition, and modeling in active manipulation approaches. We conclude with a discussion of real-life applications and directions for future research.

41.1 Perception via Manipulation

In this chapter, we focus on perceptual methods that rely on manipulation. As we will see, sensing-*via*-manipulation is a complex and highly intertwined process, in which the results of perception are used for manipulation and manipulation is used to gather additional data. Despite this complexity, there are three main reasons to use manipulation either together or instead of the more commonly used vision sensors.

First, manipulation can be used to sense in poor-visibility conditions: for example, sensing in muddy water or working with transparent objects. In fact, due to its high accuracy and ability to sense any hard surface regardless of its optical properties, contact sensing

is widely used for accurate localization of parts in manufacturing. Second, manipulation is useful for determining properties that require physical interaction, such as stiffness, mass, or the physical relationship of parts. Third, if the actual goal is to manipulate the object, we might as well use data gathered from manipulation attempts to improve both perception and subsequent attempts at manipulation.

Sensing-*via*-manipulation also faces significant challenges. Unlike vision sensors, which provide a whole-scene view in a single snapshot, contact sensors are inherently local, providing information only about a very small area of the sensed surface at any given time. In order to gather additional data, the manipu-

lator has to be moved into a different position, which is a time-consuming task. Hence, unlike vision-based perception, contact-based methods have to cope with very sparse data and very low data acquisition rates. Moreover, contact sensing disturbs the scene. While in some situations this can be desirable, it also means that each sensing action can increase uncertainty. In fact, one can easily end up in a situation where the information gained via sensing is less than the information lost due to scene disturbance.

Due to these challenges, specialized perceptual methods had to be developed for perception-via-manipulation. Inference methods have been developed to extract the most information from the scarce data and to cope with cases in which the data are insufficient to fully solve the problem (i. e., under-constrained scenarios).

41.2 Object Localization

Tactile object localization is the problem of estimating the object's pose – including position and orientation – based on a set of data obtained by touching the object. A prior geometric model of the object is assumed to be known and the sensing is performed using some type of contact sensor (wrist force/torque sensor, tactile array, fingertip force sensor, etc.). The problem is typically restricted to rigid objects, which can be stationary or moving.

Tactile object localization involves several components, including manipulator control methods, modeling, inference, and planning. During data collection, some form of sensorimotor control is used for each sensing motion of the manipulator. For information on manipulator control, the reader is encouraged to reference Chaps. 8 and 9. With few exceptions, the sensing motions tend to be poking motions rather than following the surface. This is due to the fact that robots are usually unable to sense with all parts of the manipulator, and, hence, the poking motions are chosen to minimize the possibility of accidental non-sensed contact.

Due to the properties of sensing-via-contact, special methods for modeling, inference, and planning had to be developed for tactile localization. Modeling choices include not only how to model the object itself, but also models of the sensing process and models of possible object motion. We discuss models of sensing and motion in Sect. 41.2.2, but leave an in-depth discussion of object modeling techniques until Sect. 41.3. We also cover specialized inference and planning methods in Sect. 41.2.3 and 41.2.5, respectively.

Planning methods have been developed to make the most efficient sensing decisions based on the little data available and taking into account time, energy, and uncertainty costs of sensing actions. Modeling methods have been developed to build the most accurate models from small amounts of data.

In this chapter, the material is organized by perceptual goal: localizing an object (Sect. 41.2), learning about an object (Sect. 41.3), and recognizing an object (Sect. 41.4). Since the chapter topic is broad, to keep it concise, we provide a tutorial-level discussion of object localization methods, but give a birds-eye view of the methods for the other two perceptual goals. However, as we point out along the way, many object localization methods can be reused for the other two perceptual goals.

41.2.1 Problem Evolution

Attempts to solve the tactile object localization date back to early 80s. Over the years, the scope of the problem as well as methods used to solve it have evolved as we detail below.

Early Methods

Early methods for tactile object localization generally ignore the sensing process uncertainties and focus on finding a single hypothesis that best fits the measurements. For example, *Gaston* and *Lozano-Perez* used interpretation trees to efficiently find the best match for 3 DOF (degrees of freedom) object localization [41.1]. *Grimson* and *Lozano-Perez* extended the approach to 6 DOF [41.2]. *Faugeras* and *Hebert* used least squares to perform geometrical matching between primitive surfaces [41.3]. *Shekhar* et al. solved systems of weighted linear equations to localize an object held in a robotic hand [41.4]. Several methods use geometric constraints together with kinematic and dynamic equations to estimate or constrain the pose of known planar objects in plane by pushing them with a finger [41.5] or parallel-jaw gripper [41.6], or by tilting them in a tray [41.7].

Workpiece Localization

Single hypothesis methods are also widely used to solve the workpiece localization problem in manufacturing applications for dimensional inspection [41.8], machining [41.9], and robotic assembly [41.10]. In these applications, the measurements are taken by a coordinate measurement machine (CMM) [41.11] or by on-machine sensors [41.12]. Workpiece localization makes

a number of restrictive assumptions that make it inapplicable to autonomous robot operation in unstructured environments. One important restriction is that there is a known correspondence between each measured data point and a point or patch on the object surface (called home point or home surface, respectively) [41.13]. In semiautomated settings, the correspondence assumption is satisfied by having a human direct the robot to specific locations on the object. In fully automated settings, the object is placed on the measurement table with low uncertainty to make sure each data point lands near the corresponding home point.

Further restrictions include assumptions that the data are sufficient to fully constrain the object, the object does not move, and there are no unmodeled effects (e.g., vibration, deformation, or temperature variation). All of these parameters are carefully controlled for in structured manufacturing environments.

The workpiece localization problem is usually solved in least squares form using iterative optimization methods, including the Hong-Tan method [41.14], the Variational method [41.15], and the *Menq* method [41.16]. Since these methods are prone to getting trapped in local minima, low initial uncertainty is usually assumed to make sure the optimization algorithm is initialized near the solution. Some attempts have been made to solve the global localization problem by rerunning the optimization algorithm multiple times from prespecified and random initial points [41.17]. Recent work has focused on careful selection of the home points to improve localization results [41.18–20] and on improving localization efficiency for complex home surfaces [41.21, 22].

Bayesian Methods

In the last decade, there has been increased interest in Bayesian state estimation for the tactile object localization problem [41.23–27]. These methods estimate the probability distribution over all possible states (the belief), which captures the uncertainty resulting from noisy sensors, inaccurate object models, and other effects present during the sensing process. Thus, estimation of the belief enables planning algorithms that are resilient to the uncertainties of the real world. Unlike workpiece localization, these methods do not assume known correspondences. In contrast to single hypothesis or set-based methods, belief estimation methods allow us to better describe and track the relative likelihoods of hypotheses in the under-constrained scenario, in which the data are insufficient to fully localize the object. These methods can also work with moving objects and answer important questions such as: *have we localized the object completely?* and *where is the best place to sense next?*

41.2.2 Bayesian Framework

All Bayesian methods share a similar framework. We start with a general definition of a Bayesian problem (not necessarily tactile object localization), and then, explain how this formulation can be applied to tactile localization.

General Bayesian Problem

For a general Bayesian problem, the goal is to infer the state X of a system based on a set of sensor measurements $\mathcal{D} := \{D_k\}$. Due to uncertainty, this information is best captured as a probability distribution

$$\text{bel}(X) := p(X|\mathcal{D}), \quad (41.1)$$

called the posterior distribution or the Bayesian belief. Figure 41.1a shows a Bayesian network representing all the random variables involved and all the relationships between them.

In a dynamic Bayesian system, the state changes over time, which is assumed to be discretized into small time intervals (Fig. 41.1b). The system is assumed to evolve as a Markov process with unobserved states. The goal is to estimate the belief at time t

$$\text{bel}_t(X_t) := p(X_t|\mathcal{D}_1, \dots, \mathcal{D}_t). \quad (41.2)$$

The behavior of the system is described via two probabilistic laws: (i) the measurement model $p(\mathcal{D}|X)$ captures how the sensor measurements are obtained and (ii) the dynamics model $p(X_t|X_{t-1})$ captures how the system evolves between time steps.

For brevity, it is convenient to drop the arguments in $\text{bel}(X)$ and $\text{bel}_t(X_t)$, and simply write bel and bel_t , but these two beliefs should always be understood as functions of X and X_t , respectively.

Tactile Localization in Bayesian Form

Tactile object localization can be formulated as an instance of the general Bayesian problem. Here, the

Fig. 41.1a,b Bayesian network representation of the relationships between the random variables involved in a general Bayesian problem. The directional arrows are read as *causes*. **(a)** In the static case, a single unknown state X causes a collection of measurements $\{D_k\}$. **(b)** In the dynamic case, the state X_t changes over time and at each time step causes a set of measurements \mathcal{D}_t .

Fig.41.2a,b Examples of objects (a) and their polygonal mesh models (b). Five objects are shown: cash register, toy guitar, toaster, box, and door handle. The first three models were constructed by collecting surface points with the robot's end effector. The last two were constructed from hand measurements made with a ruler. The door handle model is 2-D. Model complexity ranges from 6 faces (for the box) to over 100 faces (for the toaster) (after [41.28])

robot needs to determine the pose X of a known object \mathcal{O} based on a set of tactile measurements \mathcal{D} . The state is the 6 DOF pose of the object – including position and orientation – in the manipulator coordinate frame. A number of state parameterizations are possible, including matrix representations, quaternions, Euler angles, and Rodrigues angles, to name a few. For our discussion here, assume that the state $X := (x, y, z, \alpha, \beta, \gamma)$, where (x, y, z) is the position and (α, β, γ) are orientation angles in Euler representation.

The measurements $\mathcal{D} := \{D_k\}$ are obtained by touching the object with the robot's end effector. The end effector can be a single probe, a gripper, or a hand. Thus, it may be able to sense multiple contacts D_k simultaneously, for example, in a single grasping attempt. We will assume that for each touch D_k , the robot is able to measure the contact point and also possibly sense the normal of the surface (perhaps as the direction of reaction force). Under these assumptions, each measurement $D_k := (D_k^{\text{pos}}, D_k^{\text{nor}})$ consists of the measured Cartesian position of the contact point D_k^{pos} and the measured surface normal D_k^{nor} . If measurements of surface normals are not available, then $D_k := D_k^{\text{pos}}$.

Measurement Model

In order to interpret tactile measurements, we need to define a model of the object and a model of the sensing process. For now, assume that the object is modeled as a polygonal mesh, which could be derived from a CAD model or a 3-D scan of the object, or built using contact sensors. Examples of objects and their polygonal mesh representations are shown in Fig. 41.2. Other types of object models can also be used. We provide an in-depth look at object modeling techniques in Sect. 41.3.

Typically, the individual measurements D_k in a data set \mathcal{D} are considered independent of each other given the state X . Then, the measurement model factors over

the measurements

$$p(\mathcal{D}|X) = \prod_k p(D_k|X). \quad (41.3)$$

Sampled Models. Early Bayesian tactile localization work used sampled measurement models. For example, Gadeyne and Bruyninckx used numerical integration to compute the measurement model for a box and stored it in a look-up table for fast access [41.23]. Chhatpar and Branicky sampled the object surface by repeatedly touching it with the robot's end-effector to compute the measurement probabilities (Fig. 41.3) [41.24].

Proximity Model. One common model for the interpretation of tactile measurements is the proximity measurement model [41.29]. In this model, the measurements are considered to be independent of each other, with both position and normal components corrupted by Gaussian noise. For each measurement, the probability depends on the distance between the measurement and the object surface (hence the name *proximity*).

Fig.41.3a,b Sampled measurement model for a key lock. (a) The robot exploring the object with a key. (b) The resulting lock-key contact C-space (after [41.24])

Since the measurements contain both contact coordinates and surface normals, this distance is taken in the 6-D space of coordinates and normals (i.e., in the measurement space). Let \hat{O} be a representation of the object in this 6-D space. Let $\hat{o} := (\hat{o}^{\text{pos}}, \hat{o}^{\text{nor}})$ be a point on the object surface, and D be a measurement. Define $d_M(\hat{o}, D)$ to be the Mahalanobis distance between \hat{o} and D

$$d_M(\hat{o}, D) := \sqrt{\frac{\|\hat{o}^{\text{pos}} - D^{\text{pos}}\|^2}{\sigma_{\text{pos}}^2} + \frac{\|\hat{o}^{\text{nor}} - D^{\text{nor}}\|^2}{\sigma_{\text{nor}}^2}}, \quad (41.4)$$

where σ_{pos}^2 and σ_{nor}^2 are Gaussian noise variances of position and normal measurement components, respectively. In the case of a sensor that only measures position (and not surface normal), only the first summand is used inside the square root. The distance between a measurement D and the entire object \hat{O} is obtained by minimizing the Mahalanobis distance over all object points \hat{o}

$$d_M(\hat{O}, D) := \min_{\hat{o} \in \hat{O}} d_M(\hat{o}, D). \quad (41.5)$$

Let \hat{O}_X denote the object in state X . Then, the measurement model is computed as

$$p(D|X) = \eta \exp \left[-\frac{1}{2} \sum_k d_M^2(\hat{O}_X, D_k) \right]. \quad (41.6)$$

In the above equation and throughout the chapter, η denotes the normalization constant, whose value is such that the expression integrates to 1.  VIDEO 723 shows the proximity model being used to localize a door handle.

Integrated Proximity Model. A variation of the proximity model is called the integrated proximity model. Instead of assuming that the closest point on the object caused the measurement, it considers the contribution from all surface points to the probability of the measurement [41.25]. This is a much more complex model that in general can not be computed efficiently. Moreover, for an unbiased application of this model, we need to compute a prior over all surface points, i.e., how likely each surface point is to cause a measurement. This prior is usually nonuniform and highly dependent on the object shape, the manipulator shape, and the probing motions. Nevertheless, in some cases this model can be beneficial as it is more expressive than the proximity model.

Negative Information. The models we have described so far do not take into account negative information, i.e., information about the absence rather than presence of measurements. This includes information that the robot was able to move through some parts of space without making contact with the object. Negative information is very useful for active exploration strategies and has been taken into account by [41.26] and [41.25]. Although adding negative information makes the belief more complex (e.g., discontinuous), in most cases, it can be superimposed on top of the belief computed using one of the above measurement models.

Dynamics Model

Free-standing objects can move during probing, and hence, a dynamics model is needed to describe this process. In most situations, little is known about possible object motions, and thus, a simple Gaussian model is assumed. Hence, $p(X_t|X_{t-1})$ is a Gaussian with mean at X_{t-1} and variances σ_{met}^2 and σ_{ang}^2 along metric and angular axes respectively. If additional properties of object motion are known, then a more informative dynamics model can be used. For example, if we know the robot shape and the magnitude and direction of the contact force, we can use Newtonian dynamics to describe object motion. This motion may be further restricted, if it is known that the object is sliding on a specific surface.

41.2.3 Inference

Once the models are defined and the sensor data are obtained, the next step is to estimate the resulting probabilistic belief. This process is called inference and can be viewed as numerical estimation of a real-valued function over a multidimensional space. We can distinguish two cases: a static case where the object is rigidly fixed and a dynamic case where the object can move. The dynamic case is solved recursively at each time step using a Bayesian filter. The static case can be solved either recursively or in a single step by combining all the data into a single batch. The other important differentiator is the amount of initial uncertainty. In low uncertainty problems, the pose of the object is approximately known and only needs to be updated based on the latest data. This type of problem usually arises during tracking of a moving object, in which case it is known as pose tracking. In global uncertainty problems, the object can be anywhere within a large volume of space and can have arbitrary orientation. This case is often referred to as global localization. Global localization problems arise for static objects, when the pose of the object is unknown, or as the initial step in pose tracking of a dynamic object. It is also the fallback

whenever the pose tracking method fails and uncertainty about the object pose becomes large.

The belief tends to be a highly complex function with many local extrema. For this reason, parametric methods (such as Kalman filters) do not do well for this problem. Instead, the problem is usually solved using nonparametric methods. The complexity of the belief is caused directly by properties of the world, the sensors, and models thereof. For more insight into causes of belief complexity and appropriate estimation methods, see the discussion of belief roughness in [41.28, Chap. 1].

We start by describing basic nonparametric methods, which are efficient enough to solve problems with up to three degrees of freedom (DOFs). Then, in Sect. 41.2.4, we describe several advanced methods that have been developed to solve the full 6 DOF problem in real-time.

Basic Nonparametric Methods

Nonparametric methods typically approximate the belief by points. There are two types of nonparametric methods: deterministic and Monte Carlo (i. e., non-deterministic). The most common deterministic methods are grids and histogram filters (HF). For these methods, the points are arranged in a grid pattern with each point representing a grid cell. The most common Monte Carlo methods are importance sampling (IS) and particle filters (PF). For Monte Carlo methods, the points are sampled randomly from the state space and called samples or particles.

Static Case

Via Bayes rule, the belief $bel(X)$ can be shown to be proportional to $p(\mathcal{D}|X)p(X)$. The first factor is the measurement model. The second factor, $\overline{bel}(X) := p(X)$, is called the Bayesian prior, which represents our belief about X before obtaining measurements \mathcal{D} . Hence, with this notation, we can write

$$bel = \eta p(\mathcal{D}|X) \overline{bel}. \quad (41.7)$$

In the most common case, where it is only known that the object is located within some bounded region of space, a uniform prior is most appropriate. In this case, the belief bel is proportional to the measurement model and the equation (41.7) simplifies to

$$bel = \eta p(\mathcal{D}|X). \quad (41.8)$$

However, if an approximate object pose is known ahead of time (e.g., an estimate produced from a vision sensor), then it is common to use a Gaussian prior of some covariance around the approximate pose.

Grid methods compute the unnormalized belief $p(\mathcal{D}|X) \overline{bel}$ at the center of each grid cell and then nor-

malize over all the grid cells to obtain an estimate of the belief bel .

Monte Carlo methods use importance sampling. For uniform priors, the particles are sampled uniformly from the state space. For more complex priors, the particles have to be sampled from the prior distribution \overline{bel} . The importance weight for each particle is set to the measurement model $p(\mathcal{D}|X)$ and the entire set of importance weights is normalized so that the weights add up to 1.

Dynamic Case

Given the measurement model $p(\mathcal{D}|X)$, the dynamics model $p(X_t|X_{t-1})$, and measurements $\{\mathcal{D}_1, \dots, \mathcal{D}_t\}$ up to time t , the belief can be computed recursively using a Bayesian filter algorithm, which relies on the Bayesian recursion equation

$$bel_t = \eta p(\mathcal{D}_t|X_t) \overline{bel}_t. \quad (41.9)$$

To compute (41.9), the Bayesian filter alternates two steps: (a) the dynamics update, which computes the prior

$$\overline{bel}_t = \eta \int p(X_t|X_{t-1}) bel_{t-1} dX_{t-1}, \quad (41.10)$$

and (b) the measurement update, which computes the measurement model $p(\mathcal{D}_t|X_t)$.

A grid-based implementation of the Bayesian filter is called a histogram filter. Histogram filters compute (41.9) for each grid cell separately. At the start of time step t , the grid cell stores its estimate of the belief bel_{t-1} from the previous time step. During the dynamics update, the value of the prior \overline{bel}_t at this grid cell is computed using (41.10), where the integral is replaced by a summation over all grid cells. During the measurement update, the measurement model is computed at the center of the grid cell and multiplied by the value of the grid cell (i. e., the prior). Then, values of all grid cells are normalized so they add up to 1. Since during dynamics update, a summation over all grid cells has to be carried out for each grid cell, the computational complexity of histogram filters is quadratic in the number of grid cells.

A Monte Carlo implementation of the Bayesian filter is called a particle filter. The particle set representing the prior \overline{bel}_t is produced during the dynamics update as follows. The particles are resampled (see [41.30] for a tutorial on resampling) from the belief at the previous time step, bel_{t-1} , and then moved according to the dynamics model with the addition of some motion noise. This produces a set of particles representing the prior \overline{bel}_t . The measurement update is performed using importance sampling as in the static case above. Note that

unlike for the histogram filters, there is no per-particle summation during the dynamics update, and thus, the computational complexity of particle filters is linear in the number of particles.

41.2.4 Advanced Inference Methods

Although suitable for some problems, basic nonparametric methods have a number of shortcomings. There are two main issues.

1. While a rigid body positioned in space has 6 DOFs, the basic methods can only be used for localization with up to 3 DOFs. Beyond 3 DOFs, these methods become computationally prohibitive due to exponential growth in the number of particles (or grid cells) required. The reason for the exponential blow-up is as follows. In order to localize the object, we need to find its most likely poses, i.e., the peaks of bel_t . These peaks (also called modes) are very narrow, and, hence, the space needs to be densely populated with particles in order to locate them. The number of particles required to achieve the same density per unit volume goes up exponentially with the number of DOFs. Hence, the computational complexity of nonparametric methods also grows exponentially with the number of DOFs. This is known as the curse of dimensionality.
2. Another important issue is that the performance of basic nonparametric methods actually *degrades with increase in sensor accuracy*. This problem is especially pronounced in particle filters. Although it may seem very unintuitive at first, the reason is simple. The more accurate the sensor the narrower the peaks of the belief. Thus, more and more particles are required to find these peaks. We can call this problem curse of accurate sensor.

Several more advanced methods have been developed to combat the shortcomings of basic methods. Below, we detail one such method, called scaling series, and briefly discuss a few others.

Scaling Series

Scaling series is an inference algorithm designed to scale better to higher dimensional problems than the basic methods [41.28, Chap. 2]. In particular, it is capable of solving the full 6 DOF localization problem. Moreover, unlike for basic methods, the accuracy of scaling series *improves with increase in sensor accuracy*. For this reason, this algorithm may be preferable to basic methods even in low-dimensional problems.

Scaling series represents the belief by broad particles. Each particle is thought of as a representative for

an entire δ -neighborhood, that is, the volume of space of radius δ surrounding the sample point. Instead of fixing the total number of particles (as in the basic methods), scaling series adjusts this number as needed to obtain good coverage of main peaks.

Peak width can be controlled using annealing, which means that for a given temperature τ , the measurement model is raised to the power of $1/\tau$. Hence, for $\tau = 1$, the original measurement model is obtained, whereas for $\tau > 1$ the measurement model is *heated-up*. Annealing broadens the peaks of bel_t , making them easier to find. However, it also increases ambiguity and decreases accuracy (Fig. 41.4). To make sure that accuracy is not compromised, scaling series combines annealing with iterative refinements as we detail below.

The Static Case Algorithm. Let us first consider the case, where the prior \overline{bel} is uniform. Scaling series starts by uniformly populating the space with very broad particles (i.e., with large δ). It evaluates the annealed measurement model for each particle and prunes out low probability regions of space. Then, it refines the estimate with slightly narrower particles, and repeats again and again until a sufficiently accurate estimate is obtained. Peak width is controlled during iterations using annealing, to make sure that each particle is able to represent its δ -neighborhood well. As the value of δ decreases during iterations, the density of particles per volume of δ -neighborhood is kept constant to maintain good particle density near peaks. We can think of δ as peak width, which decreases (due to annealing) with iterations. At each iteration, the δ -neighborhood of each peak will have the same fixed number of particles.

The formal algorithm listing is given in Algorithm 41.1, where S_δ denotes a δ -neighborhood and $\dim X$ is the dimensionality of the state space. The algorithm relies on three subroutines. `Even_Density_Cover` samples a fixed number

Fig.41.4a,b True (a) and annealed (b) belief for localization of the cash register [41.28]. The cash register model is shown as a wire frame. The small colored squares represent high likelihood particles. Note that annealing makes the problem much more ambiguous

of particles from each δ -neighborhood of a volume of space. It can be easily implemented using rejection sampling. `Importance_Weights` computes normalized importance weights using the annealed measurement model $p(\mathcal{D}|X)^{1/\tau}$. The `Prune` subroutine prunes out low probability regions. This step can be done either by weighted resampling or by thresholding on the weights.

The algorithm returns an approximation of the belief represented by a weighted particle set \mathcal{X} , where the weights \mathcal{W} are set according to the measurement model, which in the case of uniform prior is proportional to the belief (41.8). Extension to the case of nonuniform prior can be done by simply multiplying the resulting weights by the prior. Sampling from the prior at the start of scaling series may also be useful. See  VIDEO 721 for an example, where scaling series is successfully applied to 6-DOF localization of a cash register.

Algorithm 41.1 Scaling series algorithm for belief estimation

Input:
 V_0 – initial uncertainty region,
 \mathcal{D} – data set,
 M – number of particles per δ -neighborhood,
 δ_* – terminal value of δ .

- 1: $\delta_0 \leftarrow \text{Radius}(V_0)$
- 2: $\text{zoom} \leftarrow 2^{-1/\dim X}$
- 3: $N \leftarrow \lfloor \log_2(\text{Volume}(S_{\delta_0})/\text{Volume}(S_{\delta_*})) \rfloor$
- 4: **for** $n = 1$ to N **do**
- 5: $\delta_n \leftarrow \text{zoom} \cdot \delta_{n-1}$
- 6: $\tau_n \leftarrow (\delta_n/\delta_*)^2$
- 7: $\bar{\mathcal{X}}_n \leftarrow \text{Even_Density_Cover}(V_{n-1}, M)$
- 8: $\mathcal{W}_n \leftarrow \text{Importance_Weights}(\bar{\mathcal{X}}_n, \tau_n, \mathcal{D})$
- 9: $\mathcal{X}_n \leftarrow \text{Prune}(\bar{\mathcal{X}}_n, \mathcal{W}_n)$
- 10: $V_n \leftarrow \text{Union_Delta_Neighborhoods}(\mathcal{X}_n, \delta_n)$
- 11: **end for**
- 12: $\mathcal{X} \leftarrow \text{Even_Density_Cover}(V_N, M)$
- 13: $\mathcal{W} \leftarrow \text{Importance_Weights}(\mathcal{X}, 1, \mathcal{D})$

Output:
 $(\mathcal{X}, \mathcal{W})$ – a weighted particle set approximating the belief.

Dynamic Case. Scaling series can be extended to the dynamic case using the same technique as in the histogram filter. During the measurement update, the measurement model is estimated using scaling series with a uniform prior. This produces a set of weighted particles \mathcal{X}_t . During the dynamics update, the importance weights are adjusted to capture the motion model via the Bayesian recursion equation (41.9). To do this,

for each particle X_t in \mathcal{X}_t , the importance weight is multiplied by the prior $\overline{\text{bel}}_t(X_t)$. Like in the histogram filter, the prior at a point X_t is computed by replacing the integral in (41.10) with a summation, except now the summation is done over all particles in \mathcal{X}_{t-1} . For other versions of dynamic scaling series, refer to [41.28, Chapter 2].

Other Advanced Inference Methods

Other advanced methods have been used to solve the tactile object localization problem, including the annealed particle filter (APF) [41.25], the GRAB algorithm [41.31], and the manifold particle filter (MPF) [41.32].

The APF algorithm is similar to scaling series as it also uses particles and iterative annealing. This algorithm was originally developed for articulated object tracking based on vision data [41.33, 34]. Unlike scaling series, APF keeps the number of particles constant at each iteration and the annealing schedule is derived from the particle set itself based on survival rate. Due to these properties, APF handles poorly in multimodal scenarios [41.35], which are prevalent in tactile object localization.

The GRAB algorithm is based on grids and measurement model bounds. It performs iterative grid refinements and prunes low-probability grid cells based on measurement model bounds. Unlike the majority of inference methods, GRAB is able to provide guaranteed results as long as the measurement model bounds are sound. It is well-suited for problems with many discontinuities, for example, whenever negative information is used in the measurement model. However, for smooth measurement models (such as the proximity model), GRAB has been shown to be slower than scaling series [41.28].

Similarly to the dynamic version of scaling series, the MPF algorithm samples particles from the measurement model and weighs them by the dynamics model. However, to sample from the measurement model, MPF draws a set of particles from the contact manifold, defined as the set of object states that contact a sensor without penetrating. Then, MPF weighs these new particles by propagating prior particles forward using the dynamics model and applying kernel density estimation. Since the contact manifold is a lower dimensional manifold than the full state space of object poses, the MPF requires fewer particles than a traditional PF. It is not yet known if the improvement is sufficient to handle the full 6 DOF problem. However, it has been shown that MPF is capable of handling accurate sensors [41.32]. While MPF provides a method for sampling from the contact manifold for a single contact, it is unclear how to ex-

tend this approach to the case of multiple simultaneous contacts.

41.2.5 Planning

In order to localize an object, we need a strategy for gathering the data. Since each touch action can take significant time to execute, it is particularly important to accomplish the task with as few touches as possible. In this section, we will cover how to generate candidate actions and how to select which action to execute, with the goal of either localizing the object or grasping it with a high probability of task success.

Candidate Action Generation

The first step in selecting actions for tactile localization is to generate a set of candidate motions. While the object's pose is uncertain, we would like to avoid knocking over the object or damaging the robot. For this reason, actions are generally guarded motions, where the robot stops moving upon detecting contact. For multifingered robots, it may be advantageous to close the fingers upon detecting contact, in order to generate more than one contact point per action.

Candidate motions can be automatically generated in a similar manner to randomized or heuristic grasp planning methods (such as [41.36] or [41.37]). This approach is particularly useful if the goal is to generate multiple fingertip contacts, because any motion that is likely to grasp the object is also likely to result in informative contacts.

One option is to generate a small pool of good candidate motions based on the object shape, and to execute them relative to the current most-likely state of the object, as in [41.38]. Another option is to generate a larger pool of motions that are fixed with respect to the world, as in [41.39]. Finally, we can generate paths that specifically target disambiguating features. For example, *Schneider* and *Sheridan* [41.40] show how to select paths that are guaranteed to disambiguate among remaining object shape and pose hypotheses, or if none such are possible, how to select paths that at least guarantee that something will be learned.

Bayesian Formulation of Planning

Once a pool of candidate actions has been created, the problem of selecting an optimal action to take next can be formulated as a partially observable Markov decision process (POMDP). Details on POMDPs can be found in Chap. 14. Briefly, a POMDP consists of a set of states $X := \{X_i\}$, a set of actions $\mathcal{A} := \{A_j\}$, a set of observations $\mathcal{D} := \{D_k\}$. Both measurement model and dynamics model from Sect. 41.2.2 are now conditioned on the action A taken. This change is clearly visible

Fig. 41.5 Bayesian network representation of the planning problem. Note how it differs from Fig. 41.1b. Measurements \mathcal{D}_t now depend on both the state X_t and the action chosen A_t . The state X_t evolves based on both the prior state X_{t-1} and the chosen action A_t

in the dynamic Bayesian network representation of the problem: compare Fig. 41.5 to Fig. 41.1b. Hence, the dynamics model is now $p(X_t|X_{t-1}, A_t)$, which is often called the transition model in the context of POMDPs. It represents the probability distribution of state X_t , given that we were in state X_{t-1} and executed action A_t . Similarly, the measurement model is now $p(D_t|X_t, A_t)$. For problems where the state X is continuous, the state space is typically discretized using either a grid or a set of particles.

For tactile object localization, the states are the actual object poses, the actions are our candidate robot motions (which may or may not touch the object), and the observations can include tactile and/or proprioceptive information gained while executing actions. We do not actually know the true underlying object pose, but at any given time t , we can estimate the uncertain belief bel_t about the object pose using methods described in Sect. 41.2.3. In the context of POMDPs, the belief is often referred to as the belief state.

A POMDP policy specifies an action A , for every possible belief. Intuitively, there is an optimal policy that would get the robot to the goal state most efficiently for any possible starting state. This optimal policy can be found using value or policy iteration algorithms. However, for the problem of tactile localization, these algorithms are typically computationally prohibitive for any practical discretization of the state space. Hence, this problem is usually solved using methods that approximate the optimal policy for a subset of states. For instance, online replanning using one-step or multi-step lookahead is nonoptimal but usually provides good results.

For a subset of tactile localization problems, one-step lookahead has been shown to be nearly optimal [41.41]. Problems in this class satisfy two assumptions: (1) the object is stationary and does not move when touched (e.g., a heavy appliance), and (2) the actions being considered are a fixed set of motions regardless of the current belief. With these as-

sumptions, tactile localization can be formulated as an adaptive submodular information-gathering problem. Adaptive submodularity is a property of information-gathering problems where actions have diminishing returns, and taking additional actions never results in loss of information.

One-Step Lookahead

One way to select the next action is to consider the expected effect of each action on the belief about the object pose. Figure 41.6 shows examples of the effect of different actions on different beliefs.

Based on the possible object poses according to the current belief bel_t , we need to consider the possible outcomes of each action A . However, the same action can result in different outcomes depending on the actual object pose, which is not known to us exactly.

Simulation Experiments. Since we can not determine the effect of action A exactly, we approximate it by performing a series of simulation experiments. Let \mathcal{X}_t be the current set of state hypotheses. For histogram filters, this can be the entire set \mathcal{X} . For particle filters, it is the current set of particles. For each particular object pose $X \in \mathcal{X}_t$, we can use a geometric simulation to determine where the hand will stop along a guarded motion A , and what observation D we are likely to see. Then, we can perform a Bayesian update of bel_t to obtain the simulated belief $\widetilde{bel}_{A,D}$ that would result if we chosen action A and observed D . Let \mathcal{D}_A denote the set of all simulated observations we obtained for an action A using these experiments.

To completely account for all possible outcomes, we need to simulate all possible noisy executions of action A and all possible resulting noisy observations D . However, restricting our consideration to the set of noise-free simulations works well in practice.

Each action A may also have an associated cost $C(A, D)$, which represents how expensive or risky it is to execute A . Note, that the action cost may depend on the observation D . For example, if the cost is the amount of time it takes to execute A , then depending on where the contact is sensed, the same guarded motion will stop at a different time along the trajectory.

Utility Function. In order to decide which action to take, we need a utility function $U(A)$ that allows us to compare different possible actions. The utility function should take into account both the usefulness of the action as well as its cost.

To localize the object, we want to reduce the uncertainty about its pose. Hence, we can measure action usefulness in terms of uncertainty of the resulting belief. Intuitively, the lower the uncertainty, the higher the usefulness of an action. The amount of uncertainty in a belief can be measured using entropy, which for a probability distribution $q(X)$ is defined as

$$H(q) := - \int q(X) \log q(X) dX. \quad (41.11)$$

For each simulated belief $\widetilde{bel}_{A,D}$, we define its utility to be a linear combination of its usefulness (i. e., certainty) and cost

$$U(\widetilde{bel}_{A,D}) := -H(\widetilde{bel}_{A,D}) - \beta C(A, D), \quad (41.12)$$

where β is a weight that trades off cost and usefulness [41.39]. Since we do not know what observation we will get after executing action A , we define its utility to be the expected utility of the resulting belief based on all possible observations

$$U(A) := \mathbb{E}_D [U(\widetilde{bel}_{A,D})]. \quad (41.13)$$

Based on the simulation experiments, this expectation can be estimated as a weighted sum over all the experiments

$$U(A) \approx \sum_{D \in \mathcal{D}_A} w_D U(\widetilde{bel}_{A,D}), \quad (41.14)$$

where the weight w_D is the probability of the state X that was used to generate the observation D . More specifically, for a grid representation of state space, each $D \in \mathcal{D}_A$ was generated using some $X \in \mathcal{X}_t$, and thus, w_D

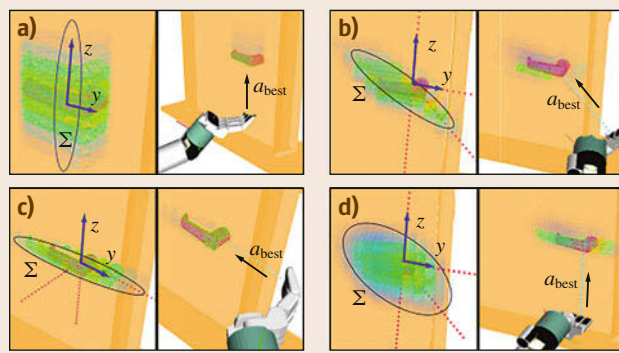

Fig.41.6a-d Selecting an action using a KLD-based utility function on examples of localizing a door handle. For each example, the starting belief bel_t is shown on the left. The action chosen $A := a_{\text{best}}$ and the resulting belief bel_{t+1} after executing the action are shown on the right. Color shows the probability of the state, ranging from high (red) to low (blue). (a) Sharp prior along the z -axis. (b) Sharp prior diagonal z - y -axis. (c) Sharp prior along the y -axis. (d) Wide prior along the diagonal z - y -axis (after [41.39])

is the belief estimated for the grid point X . If \mathcal{X}_t is represented by a set of weighted particles, then w_D is the weight of particle $X \in \mathcal{X}_t$ used to generate the observation D .

With this utility function in mind, the best action to execute is the one with the highest utility

$$A^{\text{best}} := \operatorname{argmax}_A [U(A)] . \quad (41.15)$$

Since the utility function depends on negative entropy, methods that maximize this utility function are often called entropy minimization methods.

Alternative Utility Measures. Other measures of usefulness are also possible, such as reduction in average variance of the belief or Kullback–Leibler divergence (KLD) of the simulated belief from the current belief. However, KLD is only applicable for problems where the object is stationary as this metric does not support a changing state. An example of action selection using KLD metric is shown in Fig. 41.6.

If the goal is to successfully grasp the object, not just to localize it, then it makes more sense to select actions that maximize probability of grasp success rather than simply minimizing entropy. Success criteria for grasping can, for instance, be expressed geometrically as ranges in particular dimensions of object pose uncertainty that are required for a task to succeed. For a given belief, we can add up the probabilities corresponding to the object poses (states) for which executing a desired, task-directed grasp would succeed open-loop, and maximize that value rather than minimizing entropy. Action selection can still be done using one-step-lookahead. Using this metric instead of the one in (41.12) simply allows us to concentrate on reducing uncertainty along important dimensions, while paying less attention to unimportant dimensions [41.42]. For example, the axial rotation of a nearly cylindrical object is unimportant if it only needs to be grasped successfully.

Multi-step Planning in Belief Space

While in some situations one-step-lookahead methods give good results, in other situations it may be advantageous to look more than one step ahead. This is especially true if actions take a long time to execute, and/or if the plan can be stored and reused for multiple manipulation attempts.

Multi-step lookahead can be performed by constructing a finite-depth search tree (Fig. 41.7 for illustration). Starting with the current belief bel_t , we consider possible first-step actions A_1, \dots, A_3 and simulate observations D_{11}, \dots, D_{32} . For each simulated

observation, we perform a belief update to obtain the simulated beliefs B_{11}, \dots, B_{32} . For each of these simulated beliefs, we consider possible second-step actions (of which only A_4, \dots, A_6 are shown). For each of the second-step actions, we again simulate observations and compute simulated beliefs. This process is repeated for third-step actions, fourth-step actions, and so on, until the desired number of steps is reached. The example in Fig. 41.7 shows the search tree for two-step lookahead.

After the tree is constructed from the top down to the desired depth, scoring is performed from the bottom up. Leaf beliefs are evaluated using the chosen utility metric. In the example in Fig. 41.7, the leafs shown are B_{41}, \dots, B_{62} . For each leaf, we show the entropy H and cost βC . The utility of each corresponding action A_4, \dots, A_6 is then computed by taking expectation over all observations that were simulated for that action. Note that we have to take expectations at this level because we have no control over which of the simulated observations we will actually observe. However, at the next level, we do have control over which action to execute, and we select the action with the maximum utility [41.42]. We compute the utility of beliefs B_{11}, \dots, B_{32} by subtracting their cost from the utility of the best action among their children. For example,

$$U(B_{22}) = U(A_6) - \beta C(A_2, D_{22}) . \quad (41.16)$$

In this manner, expectation and maximization can be carried out for multiple levels of the tree until the top is reached. Maximization at the very top level selects the most optimum action to execute next. Bold lines in Fig. 41.7 show the possible action sequences this algorithm would consider optimal depending on the possible observations made.

When searching to a depth greater than 1, branching on every possible observation is likely to be prohibitive. Instead, we can cluster observations based on how similar they are into a small number of canonical observations and only branch on these canonical observations.

Performing a multistep search allows us to include any desired final grasps as actions. These actions can result in early termination if the success criterion is met, but can also function as possible information-gathering actions if the criterion is not met. It also allows us to reason about actions that may be required to make desired grasps possible, such as reorienting the object to bring it within reach. As shown in [41.42], a two-step lookahead search is usually sufficient. Searching to a depth of 3 generally yields little additional benefit. One full sequence of information-gathering, grasping, and object reorientation using a multistep search with a depth of 2

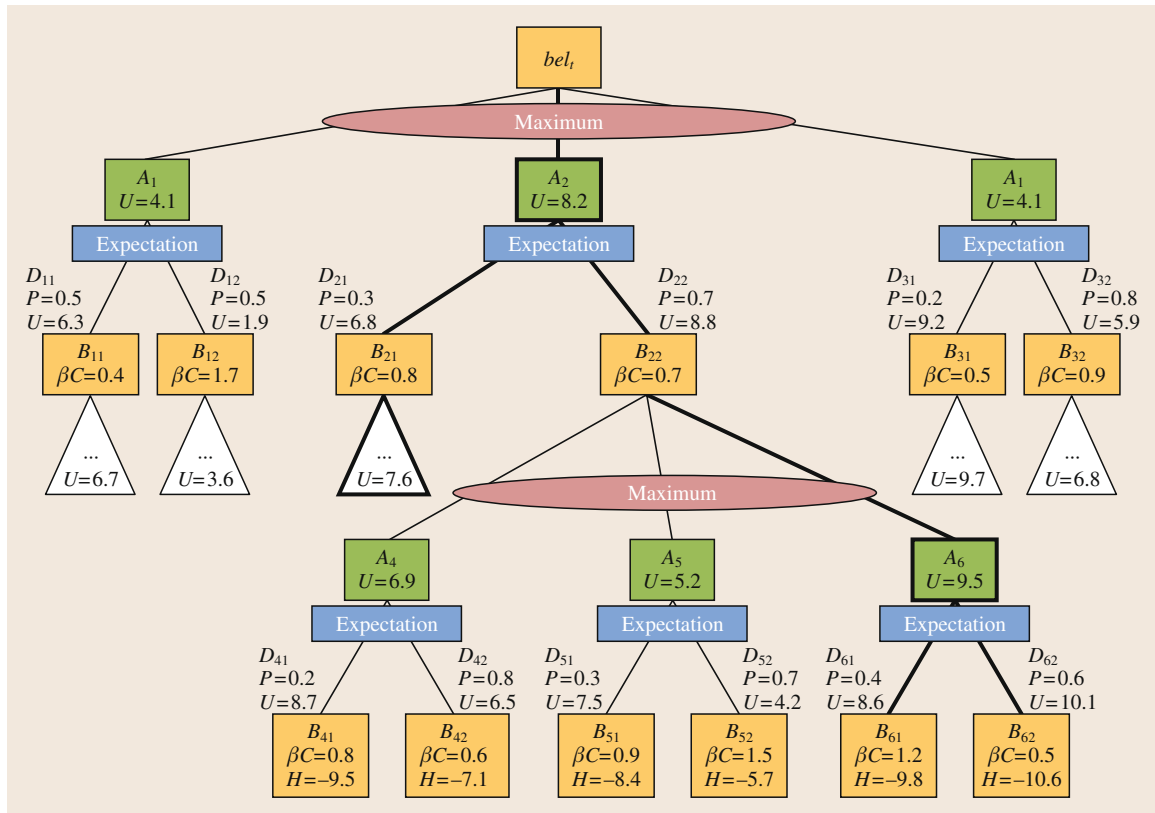

Fig. 41.7 Part of a depth-2 search tree through belief space, for three actions at each level and two canonical observations for each action; bel_t is the current belief. A_1, \dots, A_6 are actions. D_{11}, \dots, D_{62} are simulated observations. And B_{11}, \dots, B_{62} are simulated beliefs. We can compute the entropy H and action cost βC at the leaves, and thus compute the utility metric U for each leaf. Then, working upward from the bottom, we can compute the expected utility U of actions A_4, \dots, A_6 by taking a weighted sum of their children. We then select the action with maximum utility (A_6 in this example) and use its utility $U(A_6)$ to compute the utility at node B_{22} using (41.16). The same operation is repeated for the upper levels, and at the top level we finally select the action with the highest utility as the best action to be performed (A_2 in this example) (after [41.42])

for grasping a power drill is shown in Fig. 41.8, and in [VIDEO 77](#).

Other Planning Methods

There are many other possible methods for selecting actions while performing Bayesian state estimation for tactile object localization and grasping. As long as we continue to track the belief with one of the inference methods described above, even random actions can make progress toward successfully localizing the object. In this section, we will describe a few significantly different approaches to action selection for Bayesian object localization.

The planning methods we have described so far used either guarded motions or move-until-contact, to avoid disturbing or knocking over the object. However, one can instead use the dynamics of object pushing

to both localize and constrain the object's pose in the process of push-grasping, as in *Dogar and Srinivasa* [41.43].

Also, instead of using entire trajectories as actions, we could consider smaller motions as actions out of which larger trajectories could be built. In this case, one- or two-step lookahead will be insufficient to get good results. Instead, we would need to construct plans consisting of many steps. In other words, we would need a much longer planning horizon. The challenge is that searching through belief space as described above is exponential in the planning horizon. In *Platt et al.* [41.44], the authors get around this problem by assuming the current most likely state is true and searching for longer horizon plans that will both reach the goal and also differentiate the current most likely hypothesis from other sampled, competing states. If we

Fig. 41.8a-i An example sequence of grasping a powerdrill based on a depth-2 search through belief space. The *right-hand side* of each pair of images shows the grasp just executed, while the *left-hand side* shows the resulting belief. The dark blue flat rectangle and the red point-outline of the powerdrill show the most likely state, while the light blue rectangles show states that are 1 standard deviation away from the mean in each dimension (x, y, θ). Panels (a-c) and (e-g) show information-gathering grasps being used to localize the drill, panel (d) shows the robot reorienting the drill to bring the desired grasp within reach, and panels (h) and (i) show the robot using the desired final grasp on the drill, lifting, and pulling the trigger successfully (after [41.42])

monitor the belief during execution and replan whenever it diverges by more than a set threshold, the goal will eventually be reached because each hypothesis will be either confirmed (and thus the goal reached) or disproved.

Finally, while the above methods can be used for planning for what we termed *global localization* (i. e.,

object localization under high uncertainty), if the object needs to be localized in an even broader context, as when trying to locate an object somewhere in a kitchen, then we may have to plan to gather information with higher level actions (e.g., opening cabinets). Such actions could be reasoned about using symbolic task planning, as in Kaelbling and Lozano-Perez [41.45].

41.3 Learning About an Object

While the previous section focused on localization of known objects, in this section, we discuss methods for learning about a previously unknown object or environment. The goal is to build a representation of the object that can later be useful for localization, grasp planning, or manipulation of the object. A number of properties may need to be estimated, including shape, inertia, friction, contact state, and others.

41.3.1 Shape of Rigid Objects

In this set of problems, the goal is to construct a 2-D or a 3-D model of the object's geometric shape by touching the object. Due to low data acquisition rate, touch-based shape reconstruction faces special challenges as compared to methods based on dense 3-D cameras or scanners. These challenges dictate the choice of object representation and exploration strategy.

While most of the work on shape reconstruction focuses on poking motions with the end-effector, some methods rely on techniques such as rolling the object in between planar palms equipped with tactile sensors. In these methods, shape of the object can be reconstructed from the contact curves traced out by the object on the palms. These methods were first developed for planar 2-D objects [41.46], and later extended to 3-D [41.47].

Representation

The shape reconstruction process is heavily dependent on the chosen representation. Since the data are sparse, a simpler shape representation can significantly speed up the shape acquisition process.

Shape Primitives. The simplest representation is a primitive shape: plane, sphere, cylinder, torus, tetrahe-

Fig. 41.9 A combination of primitive shapes and polygonal mesh is used for modeling objects during an underwater mapping experiment (after [41.48])

dra, or cube. In this case, only a few parameters need to be estimated based on the gathered data. For example, *Slaets et al.* estimate the size of a cube by performing compliant motions with the cube pressed against a table [41.49].

Patchwork of Primitives. If one primitive does not describe the whole object well, a *patchwork* of several primitives may be used. Parts of the object are represented with subsurfaces of different primitives, which are fused together [41.48] (Fig. 41.9), [VIDEO 76](#). In this case, a strategy for refining the fusion boundaries between primitives is needed and additional data may be gathered for this specific purpose.

Super-quadrics. A slightly more complex primitive shape is a super-quadric surface, which gives more flexibility than a simple primitive. Super-quadric surfaces are surfaces described in spherical coordinates by

$$S(\omega_1, \omega_2) := \begin{pmatrix} c_x \cos^{\epsilon_1}(\omega_1) \cos^{\epsilon_2}(\omega_2) \\ c_y \cos^{\epsilon_1}(\omega_1) \sin^{\epsilon_2}(\omega_2) \\ c_z \sin^{\epsilon_1}(\omega_1) \end{pmatrix}. \quad (41.17)$$

The parameters c_x , c_y , and c_z describe the extent of the super-quadric along the axes x , y , and z , respectively. By adjusting the exponents ϵ_1 and ϵ_2 , we can vary the resulting shape anywhere from an ellipse to a box. For example, setting $\epsilon_1, \epsilon_2 \approx 0$ results in box shapes; $\epsilon_1 = 1, \epsilon_2 \approx 0$ results in cylindrical shapes; $\epsilon_1, \epsilon_2 = 1$ results in ellipses. Hence, by estimating $c_x, c_y, c_z, \epsilon_1$, and ϵ_2 , we can model a rich variety of shapes [41.50].

Polygonal Mesh. When none of the parametric representations capture the object's shape well enough, a polygonal mesh can be used. A polygonal mesh (or poly-mesh) can represent arbitrary shapes as it consists of polygons (typically, triangles) linked together to form a surface (Fig. 41.2). The simplest method is to link up collected data points to create faces (i.e., the polygons) of the mesh. However, this method tends to

under-estimate the overall size of the object because data points at object corners are rarely gathered. This effect is present even for dense 3-D sensors, but especially noticeable here due to sparsity of the data. A more accurate representation can be obtained by collecting several data points for each polygonal face and, then, intersecting the polygonal faces to obtain the corners of the mesh. However, this tends to be a more involved, manual process [41.28].

Point Cloud. Objects can also be represented as clouds of gathered data points. In this case, the accuracy of the representation directly depends on the density of the gathered data and, hence, these methods typically spend a lot of time collecting data [41.51, 52].

Splines. Two-dimensional objects can be represented by splines. For example, *Walker and Salisbury* used proximity sensors and a planar robot to map smooth shapes placed on a flat surface [41.53] (Fig. 41.10).

Fig. 41.10 A 2-D object is explored and represented by splines (after [41.53])

Volumetric Grid Maps. Objects can also be represented by volumetric grids. For 2-D objects, this representation is called an occupancy grid map. For 3-D objects, it is called a voxel grid map. Each grid cell represents a small part of the surface (or space) and records a binary value (e.g., whether the cell is occupied or not). This value is estimated based on gathered data using probabilistic methods similar to the methods used for mobile robot mapping with a 2-D laser [41.48, 54] (Fig. 41.11). For additional information on occupancy grid maps see Chap. 45.

Data Gathering

Different types of data can be collected during mapping. Tactile array images can be very informative for mapping planar objects. Sensed end-effector contact gives 3-D data points on the object surface. Link contacts can also be estimated and used for mapping even without sensory skin (Sect. 41.3.4 for more details). Moreover, the volume swept by the robot arm provides negative information, that is, the absence of obstacles in this volume. All of this information can be used both for mapping and for planning the next most informative move.

Guided Exploration. In many applications, it is acceptable to have a human operator guide the collection of data. This method allows for more accurate model building because humans can select the best points to sense on the object. Humans can also build variable accuracy models, where more data are collected near areas/features of interest and less data are collected elsewhere.

Autonomous Exploration. When autonomous model-building is required, a number of exploration strategies exist. The simplest approach is to select the sensing locations randomly. However, when using random sampling, the density of the gathered data can vary. An exhaustive strategy can ensure that points are gathered with a specified density. A triangular lattice arrangement has been shown to be the most

optimal for such a strategy; however, this method takes considerable time. The most optimal decision about the next sensing location can be made by considering the amount of information that can be gained. These techniques are similar to the techniques described in Sect. 41.2.5. Several primitive and advanced exploration strategies for tactile mapping are compared in [41.48].

41.3.2 Articulated Objects

In all the prior sections, we were concerned with rigid objects, which tend to be simpler to model. The next step up in terms of complexity are objects comprised of several rigid parts, which can move with respect to each other. These objects are called articulated objects. For many objects, the motion of connected parts with respect to each other is restricted to only one or two DOFs by prismatic or revolute joints. Examples of articulated objects include simple objects such as doors, cabinet drawers, and scissors, as well as more complex objects such as robots and even humans (Fig. 41.12).

Manipulation can play an important role in modeling novel articulated objects. By applying a force to one part of an articulated object, we can observe how the other parts move and thus infer relationships between parts. Observation can be performed via the sense of touch or via some other sense, for example, vision. For example, if a robot arm pulls/pushes a door compliantly, its trajectory allows the robot to determine the width of the door [41.57]. Alternatively, if a robot arm pushes one handle of a pair of scissors, the location of the scissors joint can be inferred by tracking visual features with an overhead camera (Fig. 41.13).

A kinematic structure consisting of several revolute and prismatic joints can be represented as a relational model, which describes relationships between object parts. In order to build a relational model of a multijoint object, a robot needs an efficient exploration strategy for gathering the data. The exploration task can be described using a Markov decision process, similar to the ones discussed in Sect. 41.2.5. Since the goal is

Fig. 41.11 Reconstruction of letters from tactile images. Pixels are colored by probability of occupancy in log-odds form. This probability can be seen to be high on the letters themselves, to be low in the surrounding area where measurements were taken, and to decay to the prior probability in the surrounding un-sensed area (after [41.54])

Fig. 41.12 Robot manipulating a variety of common articulated objects (*from left to right*): a cabinet door that opens to the right, a cabinet door that opens to the left, a dishwasher, a drawer, and a sliding cabinet door (after [41.55])

Fig. 41.13a,b Robot exploring an articulated object (after [41.56])
(a) a robot arm pushes one handle of a pair of scissors to infer the location of its joint, (b) the view from the robot's camera with tracked visual features shown as green dots

to learn relational models, these Markov decision processes (MDPs) are called relational Markov decision processes (RMDPs). With the aid of RMDPs, robots can learn efficient strategies for exploring previously unknown articulated objects, learning their kinematic structure, and later manipulating them to achieve the goal state [41.56].

Some kinematic structures do not consist entirely of revolute and prismatic joints. A common example is garage doors, which slide in and out along a curved trajectory. General kinematic models can be represented by Gaussian processes, which can capture revolute, prismatic and other types of connections between parts [41.55],  **VIDEO 78**.

41.3.3 Deformable Objects

Even more complex than articulated objects are deformable objects, which can be moved to form arbitrary shapes. The simplest of these are one-dimensional (1-D) deformable objects, such as ropes, strings, and cables. These objects are typically modeled as line objects with arbitrary deformation capability (except for stretching). A number of approaches can be found in [41.58].

A more complex type of deformable objects are planar deformable objects, such as fabric or deformable plastic sheets. While these objects can be represented as networks of nodes, modeling interaction between these nodes can get expensive and is not always necessary. For example, Platt et al. developed an approach to map planar deformable objects by swiping them between

the robot's fingers [41.59] (Fig. 41.14). These maps can later be used for localization during subsequent swipes, in a manner similar to indoor robot localization on a map.

The most complex deformable objects are 3-D deformable objects. This category includes a great variety of objects in our everyday environments: sponges, sofas, and bread are just a few examples. Moreover, in medical robotics, tissues typically have to be modeled as 3-D deformable objects. Since the stiffness and composition of these objects can vary, they need to be modeled as networks of nodes, where different interaction can take place between distinct nodes. Such

Fig. 41.14 Robot exploring a 2-D deformable object (after [41.59])

Fig.41.15a-c Model of a 3-D deformable object. The object at rest (a). The object under influence of an external force (b,c) (after [41.60])

models typically require a lot of parameters to describe even reasonably small objects. Although, some efficiency improvements can be obtained by assuming that subregions of the object have similar properties. Despite the challenges, 3-D deformable object modeling has many useful applications, for example, a surgery simulator or 3-D graphics. *Burion et al.* modeled 3-D objects as a mass-spring system (Fig. 41.15), where mass nodes are interconnected by springs [41.60]. By applying forces to the object, we can observe the deformation and infer stiffness parameters of the springs (i. e., elongation, flexion, and torsion).

41.3.4 Contact Estimation

Up until now, we have assumed that the contact location during data gathering was somehow known. However, determining the contact point is not as straightforward for robots as it is for humans, because robots are not fully covered in sensory skin. Thus, during interaction between a robot and its environment, nonsensing parts of the robot can come in contact with the environment. If such contact goes undetected, the robot and/or the environment may be damaged. For this reason, touch sensing is typically performed by placing sensors at the end-effector and ensuring that the sensing trajectories never bring nonsensing parts of the robot in contact with the environment.

Clearly, end-effector-only sensing is a significant constraint, which is difficult to satisfy in real-world conditions. Work on whole-body sensory skin is ongoing [41.61], yet for now only small portions of the robot's surface tend to be covered with sensory skin.

In lieu of sensory skin, contact can be estimated from geometry of the robot and the environment via active sensing with compliant motions. Once a contact between the robot and the environment is detected (e.g., via deviation in joint torques or angles), the robot switches to the active sensing procedure. During this procedure, the robot performs compliant motions (either in hardware or software), by applying a small force toward the environment and moving back and forth. Intuitively, the robot's body carves out free space as it moves, and thus, via geometrical reasoning, the shape

of the environment and contact points can be deduced. However, from a mathematical perspective, this can be done in several different ways.

One of the earliest approaches was developed by *Kaneko and Tanie*, who formulated the self-posture changability (SPC) method [41.63]. In SPC, the intersection of finger surfaces during the compliant motions is taken to be the point of contact. This method works well in areas of high curvature of the environment (e.g., corners), but can give noisy results in areas of shallow curvature. In contrast to SPC, the space sweeping algorithm by *Jentoft and Howe* marks all points on finger surfaces as possible contact, and then gradually rules out the possibilities [41.62] (Fig. 41.16). The space sweeping algorithm provides less noisy estimates in areas of shallow curvature, but can be more susceptible to even the smallest disturbances of the environment's surface.

Mathematically, contact estimation can also be formulated as a Bayesian estimation problem. If the robot moves using compliant motions as described above, the

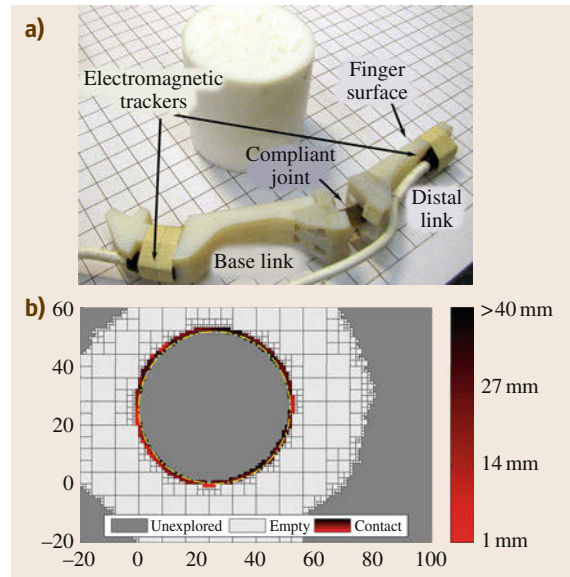

Fig. 41.16 (a) A two-link compliant finger used for contact sensing. (b) The resulting model built by the space sweeping algorithm (after [41.62])

sensor data are the joint angles of the robot. The state is the shape and position of the environment, represented using one of the rigid object models described in Sect. 41.3.1. Then, each possible state can be scored using a probabilistic measurement model, for example, the proximity model described in Sect. 41.2.2, and the problem can be solved using Bayesian inference methods [41.64].

41.3.5 Physical Properties

Up until now, we have focused on figuring out the shape and articulation of objects. While there are some advantages to doing so with tactile data as opposed to visual data, visual data can also be used to generate shape and articulation models. However, there are many properties of objects that are not easily detectable with vision alone, such as surface texture and friction, inertial properties, stiffness, or thermal conductivity.

Friction and Surface Texture

Surface friction, texture, and roughness can be estimated by dragging a fingertip over the object. The forces required to drag a fingertip over a surface at different velocities can be used to estimate surface friction parameters [41.65–67]. Accelerometer or pressure data is useful for estimating surface roughness (by the amplitude and frequency of vibration while sliding) [41.67, 68], or more directly identifying surface textures using classification techniques such as support vector machines (SVMs) or *k*-nearest neighbours (*k*-NNs) [41.69]. The position of the fingertip being dragged across the surface is also useful for estimating surface roughness and for mapping out small surface features [41.65]. Static friction is also often estimated as a by-product of trying to avoid object slip during a grasp, based on the normal force being applied at the moment when slip happens [41.70, 71]. Finally, the support friction distribution for an object sliding on a surface can be estimated by pushing the object at different locations and seeing how it moves [41.53, 72].

41.4 Recognition

Another common goal of touch-based perception is to recognize objects. As with more typical, vision-based object recognition, the goal is to identify the object from a set of possible objects. Some methods assume known object shapes and try to figure out which object geometry matches the sensor data best. Other methods use feature-based pattern recognition to identify the object, often with a bag-of-features model that does not rely

Inertia

Atkeson et al. [41.73] estimate the mass, center of mass, and moments of inertia of a grasped object, using measurements from a wrist force-torque sensor. Objects that are not grasped but that are sitting on a table can be pushed; if the pushing forces at the fingertips are known, the object's mass as well as the center of mass (COM) and inertial parameters in the plane can be estimated. Yu et al. [41.74] do so by pushing objects using two fingertips equipped with force/torque sensors and recording the fingertip forces, velocities, and accelerations. Tanaka and Kushihaman [41.75] estimate the object's mass by pushing the object with known contact force and watching the resulting motion with a camera.

Stiffness

Identifying the stiffness (or the inverse, compliance) of an object is useful in terms of modeling the material properties of an object, but more directly, it is also useful for preventing the robot from crushing or damaging delicate objects. Gently squeezing an object and measuring the deflection seen for a given contact normal force is one method often used to estimate stiffness [41.68, 76, 77]. Omata et al. [41.78] use a piezoelectric transducer and a pressure sensor element in a feedback circuit that changes its resonant frequency upon touching an object, to estimate the object's acoustic impedance (which varies with both object stiffness and mass). Burion et al. [41.60] use particle filters to estimate the stiffness parameters of a mass-spring model for deformable objects, based on the displacements seen when applying forces to different locations on the object.

Thermal Conductivity

Thermal sensors are useful for identifying the material composition of objects based on their thermal conductivity. Fingertips with internal temperature sensors [41.68, 79] can estimate the thermal conductivity of the object by heating a robot fingertip to above room temperature, touching the fingertip to the object, and measuring the rate of heat loss.

on geometric comparisons to overall object shape. Finally, there are methods that use object properties such as elasticity or texture to identify objects.

41.4.1 Object Shape Matching

Any of the methods for shape-based localization can also be used for recognition, by performing localiza-

tion on all potential objects. In terms of the equations used in Sect. 41.2, if we are considering a limited number of potential objects with known mesh models, we can simply expand our state space to include hypotheses over object identity and pose, instead of just pose. If we add an object identifier (**ID**) to each state in the state vector \mathbf{X} , and use the appropriate mesh model for that object **ID** for the measurement model for each state, all of the equations used in the previous sections still hold. The object **ID** for the combined object shape and pose that best matches the collected sensor data is then our top object hypothesis.

Nonprobabilistic methods for localization and object recognition often involve geometrically pruning objects from a set of possible object shapes/poses that do not match sensed data. For instance, *Gaston and Lozano-Perez* [41.1] and *Grimson and Lozano-Perez* [41.2] recognize and localize polyhedral objects by using the positions and normals of sensed contact points in a generate-and-test framework: generate feasible hypotheses about pairings between sensed contact points and object surfaces, and test them for consistency based on constraints over pairs of sensed points and their hypothesized face locations and normals. *Russell* [41.80] classify tactile array images as point, line, or area contacts, and use the time-sequence of contacts seen when rolling the object over the array to prune inconsistent object shapes.

Other methods recognize objects by forming a model of the object, then matching the new model with database objects. For instance, *Allen and Roberts* [41.81] build superquadric models of the object from contact data, then match the superquadric parameters against a database of object models. *Caselli et al.* [41.82] build polyhedral representations of objects (one based on contact points and normals that represents the space that the true object must fit inside, and one based on just contact points that the true object

must envelop), and use the resulting representations to prune incompatible objects in a database of polyhedral objects.

41.4.2 Statistical Pattern Recognition

Many methods for tactile object recognition use techniques from statistical pattern recognition, summarizing sensed data with features and classifying the resulting feature vectors to determine the identity of the object. For instance, *Schöpfer et al.* [41.84] roll a tactile array over objects along a straight line, compute features such as image blob centroids and second or third moments over the resulting time series of tactile images, and use a decision tree to classify objects based on the resulting features. *Bhattacharjee et al.* [41.85] use k -nearest-neighbors on a set of features based on time series images from a forearm tactile array to identify whether an object is fixed or movable, and rigid or soft, in addition to recognizing the specific object.

Tactile array data is very similar to small image patches in visual data, and so techniques for object recognition using tactile arrays can look much like object recognition techniques that use visual data. For instance, *Pezementi et al.* [41.86] and *Schneider and Sturm* [41.83] both use a Bag-of-Features model on fingertip tactile array data to recognize objects. The process for tactile data is almost the same as for visual images: for each training object (image), a set of tactile array images (2-D image patches) is obtained (Fig. 41.17), features (which are vectors of descriptive statistics) based on each tactile image are computed, and the features for all objects in the training set are clustered to form a vocabulary of canonical features (Fig. 41.18). Each object is represented as a histogram of how often each feature occurs. When looking at a new unknown object, the features computed from the tactile array images are similarly used to compute a his-

Fig. 41.17 Some objects and their associated tactile images for both left and right fingertips (after [41.83])

Fig. 41.18 Vocabulary of tactile images created using unsupervised clustering. Only the left finger's image is shown for each pair (after [41.83])

togram, and then the new histogram is compared against those of the objects in the database to find the best match. The one notable difference in the two domains is that tactile data is much more time-consuming and difficult to obtain than appropriate image patches: in 2-D visual object recognition, an interest point detection algorithm can quickly produce hundreds of salient patches from a given 2-D image, whereas for tactile object recognition, each tactile array requires touching the object, which in turn requires a planner (such as the ones described in Sect. 41.2.5) to decide how to gather appropriate tactile data.

Tactile object exploration also allows one to gather and use information besides just tactile image patches: for instance, *Gorges and Navarro* [41.87] envelop objects in a multifingered hand, and use the resulting joint angles as features that directly relate to object dimensions, alongside additional features computed from tactile image patterns. In [41.88], *Pezzementi and Hager* combine techniques from vision-based object recognition with the type of Bayesian recognition-by-localization described in Sect. 41.4.1, using pairs of fingertip tactile image features along with their positions and surface normals to update a belief state over object poses and identities.

41.4.3 Recognition by Material Properties

Tactile object recognition sometimes has significant advantages over purely visual object recognition, particularly in cases where objects are visually similar but have different material properties detectable by tactile sensors. A number of recent methods classify objects using properties such as elasticity, surface texture, and thermal conductivity. Any of the methods listed in Sect. 41.3.5 can be used to identify objects, using many of the techniques described in Sect. 41.4.2. For instance, surface texture and roughness can be used to distinguish objects, as in [41.69] or [41.67], as can thermal conductivity, as in [41.79].

More specific properties can also be used to classify objects of particular types: for instance, *Chitta et al.* [41.89] identify bottles and also classify them as open or closed, full or empty by squeezing and rolling them from side to side and using decision tree classifiers on the resulting tactile measurements. *Drimus et al.* [41.90] also identify objects by squeezing them, but using k -nearest neighbor on the time series data of tactile measurements after performing dynamic time warping to align them.

41.4.4 Combining Visual and Tactile Sensing

Of course, visual object recognition also has advantages over purely tactile methods, and so combining data from both modalities can lead to even better object recognition and localization. For instance, *Allen* [41.91] uses sparse stereo data to provide regions of interest to explore with tactile sensors, then fuses the stereo data with the resulting tactile points to create surface and feature descriptions, which are then matched against objects in the database; object hypotheses are further verified with tactile exploration. *Boshra and Zhang* [41.92] recognize polyhedral objects by using tactile features and visual vertices and edges to formulate constraints in a constraint-satisfaction problem. *Nakamura* [41.93] grasps objects and learns object categories based on visual data (in the form of SIFT descriptors), audio information obtained while shaking (using a codebook of audio features based on mel-frequency cepstral coefficients), and haptic information obtained while squeezing (using hardness estimates based on finger pressure sensor readings); the learning and inference are done using probabilistic latent semantic analysis (PLSA).

Segmenting an object from a visual scene (which makes further efforts at recognition much easier) is also made easier by combining visual and tactile sensing; by pushing on an object and seeing which parts of the visual scene move together, objects can be segmented both from the background and from each other. For instance, *Gupta and Sukhatme* [41.94] use RGB-D data along with manipulation primitives such as spreading motions to segment and sort Duplo bricks, and *Hausman et al.* [41.95] segment textureless objects in RGB-D data by performing visual segmentation and then resolving ambiguities using pushing motions.

Work on categorizing objects by their affordances or functions often also uses both visual and tactile data. For instance, *Sutton et al.* [41.96] uses both shape-based reasoning (using shape derived from range images) as well as interaction-based reasoning (using data from the robot physically interacting with the object) to predict and confirm object affordances such as grasping, containing, and sitting (being suitable for humans to sit upon). *Bekiroglu* [41.97] performs inference on a Bayesian network using visual, proprioceptive, and tactile data to assess whether an object/grasp combination will be both stable and also good for a task such as pouring, hand-over, or dishwashing.

41.5 Conclusions

This chapter described perceptual methods that rely on manipulation. Although these methods are generally more complex than vision-based perception, they are useful in low-visibility conditions, in determining properties that require manipulation, and in situations where perception is needed for subsequent manipulation tasks. Perception-via-manipulation faces special challenges due to the low data acquisition rate and the fact that each sensing action disturbs the scene. To address these challenges, special inference methods have been developed to cope with situations where data are insufficient to fully constrain the problem (Sect. 41.2.3). Special planning methods had to be applied to minimize the number of sensing actions and reduce the possibility of significant scene disturbance or non-sensed contacts (Sect. 41.2.5). These challenges also dictate the choice of object models (Sect. 41.3), and play a role in object recognition methods (Sect. 41.4).

41.5.1 Real-Life Applications

Perception-via-manipulation is already used in a number of real-world applications and an even greater number of applications will likely benefit from it in the near future. In manufacturing, touch-based localization of parts for machining or assembly is often preferred to optical methods because it is not affected by optical properties of objects (e.g., transparency or reflectivity). At present, low uncertainty in part positioning is required prior to touch-based localization, which leads to high instrumentation and reconfiguration costs. However, the new localization methods presented in this chapter can cope with high uncertainty and thus enable flexible manufacturing lines capable of producing a variety of parts without reconfiguration. In the future, fully automated in-home manufacturing may even become possible.

Medical robotics is another mature real-world application, in which robotic contact with the environment (i.e., the patient) is not only unavoidable, it is in fact required for many of the procedures. Visibility is often poor, and sensing with devices that emit sound, light, or other waves can be harmful to the patient. Under these conditions, sensing-via-contact can sometimes be the most viable option. The environment is inherently deformable, and thus, medical robotics has been a strong driver for research on manipulation and perception of deformable objects.

Another area in which robots are indispensable is underwater robotics. It is not always safe or convenient for humans to be performing tasks deep underwater,

and hence, remotely operated robots (ROVs) are a natural choice. ROVs even made international news during recovery operations from the BP oil spill disaster in the spring of 2010. Since visibility underwater is often poor, perception-via-contact plays an even more important role.

Beyond the more established robotic applications, as the fields of service robotics and disaster recovery develop, the necessity of sensing-via-contact becomes more and more obvious. In these applications, robots often have to work in clutter and in close proximity to humans. Under these conditions, visibility can be poor, yet at the same time, unsensed contact can be disastrous.

41.5.2 Future Directions of Research

Inspired by the many existing and potential applications, the field of perception-by-manipulation is evolving and receiving more attention. Despite the challenges, there are bountiful opportunities for further fruitful research:

- The vast majority of touch-based perception work deals with rigid objects, whereas many objects in our environments are articulated and/or deformable. These types of objects need to be studied in more detail.
- For rigid objects, touch-based perception of moving objects, object piles, and objects in clutter has been under-explored.
- Whole-body contact estimation needs further attention, with or without sensory skin. The challenges here are significant, but good solutions would increase the safety of robots in service applications and other unstructured environments.
- Last but not least, while Bayesian methods have found wide acceptance in other areas of robotics, touch-based perception has yet to fully benefit from these methods. Thus, application of Bayesian methods to any of the above listed areas is particularly promising.

41.5.3 Further Reading

For a broader view, a lot of related material can be found in other chapters throughout this handbook. Most sensing-via-manipulation is done using contact or near-contact (i.e., close-range) sensors. These sensors are described in Chap. 28. A few approaches use classical vision sensors in conjunction with manipulation (as in

Sect. 41.3.2, for example). Vision sensors and methods are covered in Chaps. 32 and 34. Manipulator design and control are covered in Chaps. 4, 8, and 9. Other

relevant chapters include 7, 14 and 47 for planning methods, 37, 45, and 46 for modeling, 33 for recognition, 5 and 35 for inference.

42. Haptics

Blake Hannaford, Allison M. Okamura

The word *haptics*, believed to be derived from the Greek word *haptesthai*, means *related to the sense of touch*. In the psychology and neuroscience literature, haptics is the study of human touch sensing, specifically via *kinesthetic* (force/position) and *cutaneous* (tactile) receptors, associated with perception and manipulation. In the robotics and virtual reality literature, haptics is broadly defined as real and simulated touch interactions between robots, humans, and real, remote, or simulated environments, in various combinations. This chapter focuses on the use of specialized robotic devices and their corresponding control, known as *haptic interfaces*, that allow human operators to experience the sense of touch in remote (teleoperated) or simulated (virtual) environments.

Haptic technology is intimately connected with robotics through its reliance on dexterous mechatronic devices and draws heavily on the theoretical foundations of manipulator design, actuation, sensing, and control. In this chapter, we begin with motivation for haptic interface design and use, including the basic design of a haptic interface, information about human haptics, and examples of haptic interface applications. Next, we review concepts in the mechatronic design of kines-

thetic haptic interfaces, including sensors, actuators, and mechanisms. We then examine the control aspect of kinesthetic haptic interfaces, particularly the rendering of virtual environments and stable and accurate display of forces. We next review tactile displays, which vary widely in their design due to the many types of tactile information that can be presented to a human operator. Finally, we provide resources for further study of haptics.

42.1 Overview

Haptics is the science and technology of experiencing and creating touch sensations in human operators. Imagine trying to button a coat, shake someone's hand, or write a note without the sense of touch. These simple tasks become extremely difficult to perform without adequate haptic feedback. To improve human operator performance in simulated and teleoperated environments, haptic interfaces seek to generate a compelling sensation that the operator is directly touching a real environment.

Haptic interfaces attempt to replicate or enhance the touch experience of manipulating or perceiving a real environment through mechatronic devices and computer control. They consist of a haptic device (HD, a manipulandum with sensors and actuators) and a control computer with software relating human operator inputs to haptic information display. While the low-level design of haptic interfaces varies widely depending on the application, their operation generally follows the *haptic loop* shown in Fig. 42.1. First, the haptic device senses an operator input, which may be position (and its derivatives), force, muscle activity, etc. Second, the sensed input is applied to a virtual or teleoperated environment. For a virtual environment, the effect of the operator's input on virtual objects and the subsequent response to be displayed to the operator are computed based on models and a *haptic rendering* algorithm. In teleoperation, a manipulator that is remote in space, scale, or power attempts to track the operator's input. When the manipulator interacts with its real environment, haptic information to be relayed to the operators is recorded or estimated. Finally, *actuators* on the haptic device are used to physically convey touch sensations to the human operator. Based on the haptic feedback, whether through unconscious or conscious human control, or simply system dynamics, the operator input is modified. This begins another cycle of the haptic loop.

Despite the simplicity of the concept of haptic display, there exist many challenges to developing compelling haptic interfaces. Many of these are addressed through fundamental robotics theory and an understanding of human haptic capabilities. In general, haptic interface performance specifications are based on human sensing and motor control characteristics. One major challenge in artificially generating haptic sensations is that the human operator's motion should be unrestricted when there is no contact with a virtual or remote object. Haptic devices must allow the human operator to make desired motions, thus requiring back-drivability and sufficient degrees of freedom of motion. A variety of robotic designs are used in haptic devices, including exoskeletons, actuated grippers, parallel and serial

manipulators, small-workspace *mouse*-like devices, and large-workspace devices that capture whole arm, and even whole body, movement. Another challenge is that humans integrate kinesthetic (force/position) and cutaneous (tactile) information with motion and control cues to form haptic perceptions. Haptic devices would ideally include both force and tactile displays, although this has been rarely done due to size and weight limitations of actuators. Because of the human's sensitivity to high-frequency information, for many haptic interfaces and applications, this loop must repeat at a high

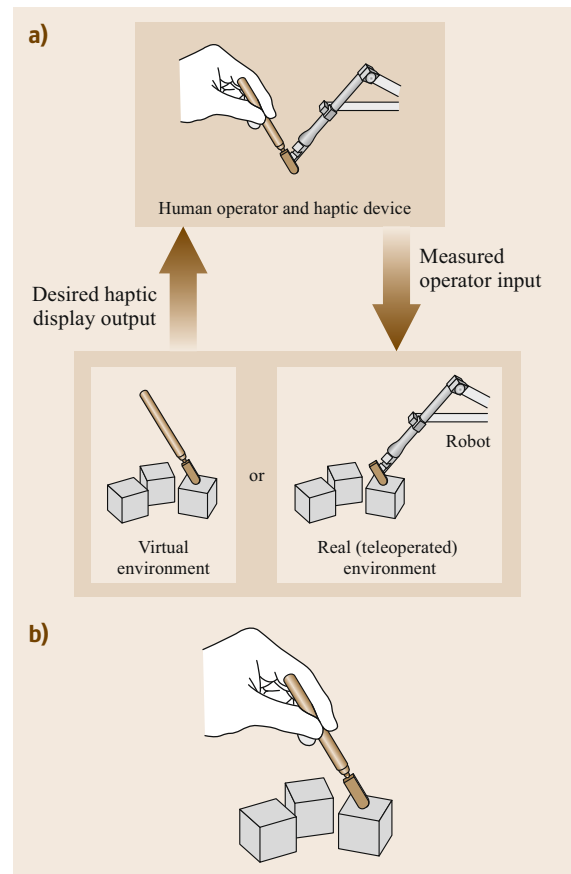

Fig. 42.1 (a) The *haptic loop* of a generic haptic interface. A haptic device senses human operator input, such as position or force, and the system applies this input to a virtual or teleoperated environment. The response of the environment to be relayed to the human operator is computed through models, haptic rendering, sensing, and/or estimation. Finally, actuators on the haptic device display corresponding touch sensations to the human operator. **(b)** The ideal result is that the human operator feels that he or she is interacting directly with a real environment

frequency, typically 1 kHz. Not only does a high update rate provide realistic (nondiscretized) touch sensations to the human operator, it also typically helps to maintain system stability. Controls analysis for haptic devices must consider both the continuous nature of the physical dynamics and the discrete nature of the computer control.

Before we examine the various components of haptic interfaces in detail, it is useful to motivate their design through a review of human haptics and applications of haptics. The remainder of this section is devoted to those topics.

42.1.1 Human Haptics

Two functions of the human nervous system play a primary role in haptics: kinesthesia (the internal sensing of forces and displacements inside muscles, tendons, and joints), and tactile sensing (the sensation of deformations of the skin).

Anatomy and Physiology

Haptics incorporates both, and is associated with an activity such as manipulation or exploration. Most of this chapter will address systems meant to interact primarily with the kinesthetic modality. Devices specifically aimed at tactile perception are described in Sect. 42.5. Even if tactile stimuli are not explicitly generated by a haptic device, tactile receptors are still stimulated, and are known to respond to frequencies as high as 10 000 Hz [42.1] and displacements as small as 2–4 μm [42.2–4].

Kinesthesia is mediated by muscle spindles, which transduce stretch of muscles, and Golgi tendon organs, which transduce joint rotation, especially at the extremes of motion. In principle, these and similar receptors could be stimulated directly to produce haptic sensations. For example, a vibration applied to a muscle tendon creates a strong sensation of muscle lengthening and corresponding joint motion in humans [42.5, 6]. Research in peripheral nerve stimulation for prosthesis control has demonstrated that electrodes implanted within individual fascicles of peripheral nerve stumps in amputees can be stimulated to produce sensations of touch or movement referred to the amputee's phantom hand [42.7].

Psychophysics

At the next level up from physiology and anatomy, psychophysics [42.8], the science of the physical capabilities of the senses, has been a rich source of design data for haptic device development. Its chief contribution has been methodologies that haptics researchers have applied to answer questions about what capa-

bilities are needed in haptic devices. These sensory capabilities could then be translated into design requirements. Some of the chief psychophysical methods that have been fruitfully applied to haptics include threshold measurement by the method of limits and adaptive up-down methods. However, perception at threshold is not 100% reliable. Perception accuracy tends to depend on the strength of the stimulus, and the tradeoff between hit rate and false alarms depends strongly on the probability that a stimulus will be present in a given time interval (P_{stim}).

A more general notion is the receiver operating curve (Fig. 42.2, borrowed by psychophysics from radar theory), which plots the probability of a subject response given the existence of a stimulus, versus the probability of response given no stimulus. The curve is generated by measuring both probabilities at several different values of P_{stim} . The ideal response is the point (0,1): 100% response for stimuli and 0% response for nonstimuli. Human response is near this point for stimuli much above threshold, but declines to a rounded curve and eventually the 45° line as response below threshold becomes equal to chance.

Another relevant concept from psychophysics is the just noticeable difference (JND), commonly expressed as a percentage. This is the magnitude of a relative change in a stimulus, such as a force or displacement applied to the finger that is just perceivable by subjects.

Fig. 42.2 Receiver operating curve (ROC). The ROC encodes the tradeoffs made by a subject between risk of false alarm and risk of missing a valid stimulus. Each point encodes a specific tradeoff between these two risks observed when stimuli are presented with a specified probability. ROCs for stronger signals tend towards the upper left hand corner (after [42.8] with permission from Lawrence Erlbaum and Associates, Mahwah)

For example, Jones [42.9] has measured JNDs of 6% for force applied to the human finger over a range of 0.5–200 N.

Psychology: Exploratory Procedures

In influential research starting in the 1980s, Lederman and Klatzky defined stereotyped hand motions called *exploratory procedures* (EPs), which are characteristic of human haptic exploration [42.10–12]. They placed objects into the hands of blindfolded subjects, and videotaped their hand motions. Their initial experiments [42.11] showed that the EPs used by subjects could be predicted based on the object property (texture, mass, temperature, etc.) that the subjects needed to discriminate. They also showed that the EPs chosen by subjects were the ones best able to discriminate that property. Furthermore, when asked to answer specific questions about objects (*Is this an eating utensil, further a fork?*), subjects used a two-stage sequence in which a more general lifting EP preceded more specific EPs [42.12].

Lederman and Klatzky's eight EPs (Fig. 42.3) and the property for which they are optimal are:

1. Lateral motion (texture)
2. Pressure (hardness)
3. Static contact (temperature)
4. Unsupported holding (weight)
5. Enclosure (global shape, volume)
6. Contour following (exact shape, volume)
7. Part motion test (part motion)
8. Function testing (specific function).

Each of these EPs is a bimanual task involving contact with all interior surfaces of the hand, motion of the wrist and various degrees of freedom of the hand, and tactile and temperature sensors in the skin (e.g., EPs 1 and 3), and kinesthetic sensors in the arm (EP 4). A haptic device capable of supporting all of these EPs is far beyond today's state of the art. However, the significance of these results for the design of haptic interface is great, since they allow us to derive device requirements from EPs.

42.1.2 Application Examples

The most common haptic device encountered by the general population is a vibration display device that provides haptic feedback while an operator plays a video game. For example, when the operator drives off the virtual road or bumps into a virtual wall, the hand controller shakes to imply driving over a rough surface or displays an impulse to represent the shock of hitting a hard surface. We examine two more pragmatic

examples, medical simulators and computer-aided design (CAD) systems, in detail below. In addition, we review several commercially available haptic devices. Although haptic interfaces are not yet in widespread commercial use outside of entertainment, they are being integrated into numerous applications where the potential benefits are clear enough to justify the adoption of new technologies. A variety of novel and creative applications are being developed regularly in numerous fields, including:

- Assistive technology
- Automotive
- Design
- Education
- Entertainment
- Human–computer interaction
- Manufacturing/assembly
- Medical simulation
- Micro/nanotechnology
- Molecular biology
- Prosthetics
- Rehabilitation
- Scientific visualization
- Space
- Surgical robotics.

Medical Simulations

A major example driving much of today's haptic virtual environment research is simulation for training of hands-on medical procedures. Medical invasive thera-

Fig. 42.3a–d Four of the eight human exploratory procedures (EPs). (a) Lateral motion (texture); (b) pressure (hardness); (c) static contact (temperature); (d) unsupported holding (weight) (after Lederman and Klatzky [42.11])

peutic and diagnostic procedures, ranging from drawing blood samples to surgery, are potentially dangerous and painful for the patient and require the student to learn hands-on skills mediated by haptic information pathways [42.13]. Simulators both with and without haptic feedback aim to replace supervised learning directly on human patients or on animals. Simulators have proven highly effective in developing minimally invasive surgery skills [42.14], especially when haptic feedback is provided in early training [42.15]. Expected benefits of training with haptic simulators include:

- Reduced risk to patients both during and immediately after training
- Increased ability to simulate unusual conditions or medical emergencies.
- Ability to collect physical data during the training process and provide specific and directed feedback to the student.
- Increased training time per unit of instructor effort.

Approaches for simulator designs, specific medical applications, and training evaluation methods have also been widely studied in the last two decades, e.g., [42.16, 17]. However, the costs of this technology are still high. In addition, it is not always clear which improvements in simulator technology, such as haptic device performance or accuracy of soft-tissue modeling, lead to improved clinical performance and, ultimately, patient outcomes.

Computer-Aided Design

The Boeing Company [42.18] has studied the use of haptic interfaces for solving advanced problems in CAD. One such problem is verification of the ability to efficiently maintain a complex system such as an aircraft. In the past, mechanics could verify the procedures (such as change-out of parts) on a physical prototype. However, this analysis is difficult or impossible to perform visually on an advanced CAD system. The VoxMap Pointshell system (Fig. 42.4) was developed to allow test extraction of parts with a haptic interface. Force sensations from the haptic interface reproduce for the operator the physical constraints of the part bumping into elements of the complex workplace. If the operator can remove the part in the haptic interface, it is verified that this part can be maintained without undue disassembly of the aircraft. This capability has been proved useful in actual design activities.

Commercially Available Haptic Devices and Systems

There are a wide variety of haptic devices available from companies, although many researchers build their

own haptic devices for special purposes. At the time of this writing, one of the most popular commercially available haptic devices is the Geomagic Touch [42.19], formerly known as the Phantom Omni from SensAble Technologies (Fig. 42.5). In the 1990s and 2000s, SensAble developed the Phantom line of stylus-type haptic devices. The Phantom Premium [42.20], a higher fidelity, larger workspace device, has also been used widely in haptics research. The high price of haptic devices (compared to visual displays) restricts the development of some commercial applications. The Geomagic Touch (Phantom Omni), which is an order of magnitude less expensive than the Phantom Premium, has gained popularity among haptics and robotics re-

Fig. 42.4 Boeing computer-aided design (CAD) application for assembly and maintenance verification of complex aircraft systems. Boeing researchers developed the Voxmap/Pointshell software for haptically rendering very complex models in six degrees of freedom at high rates (courtesy of Bill McNeely, Boeing Phantom Works)

Fig. 42.5 The Phantom Omni device from SensAble Technologies, now marketed as the Geomagic Touch. This relatively low-cost device senses motion in six degrees of freedom from the stylus and can apply forces in the x , y , and z directions to the stylus tip (courtesy SensAble Technologies, Inc., Woburn)

searchers. In 2007, Novint Technologies [42.21] released the Novint Falcon, an inexpensive 3-DOF (three-degree-of-freedom) haptic device that is in turn an order of magnitude less expensive than the Phantom Omni.

Immersion has aimed at the mass market and consumer segments with a wide variety of haptics-based products, many of them involving a single degree of freedom. For example, they have licensed technology to makers of various video games, as well as mobile phone manufacturers, in the form of vibratory feedback in handheld devices and haptic-enabled steering wheels

for driving games. Immersion also has a medical division selling medical simulators with haptic feedback.

Software for haptic rendering has also become widely available, through both commercial sources and research groups. Most companies that sell haptic devices also provide a standard development kit (SDK) with haptic rendering capability. In addition, not-for-profit open-source projects such as Chai3D [42.22] aim to make rendering algorithms from different groups publicly available, shortening application development time and allowing direct comparison of algorithms for benchmarking purposes.

42.2 Haptic Device Design

There are two broad classes of haptic devices: *admittance* and *impedance* devices. Admittance devices sense the force applied by the operator and constrain the operator's position to match the appropriate deflection of a simulated object or surface in a virtual world. In contrast, an impedance haptic device senses the position of the operator, and then applies a force vector to the operator according to computed behavior of the simulated object or surface.

Robots of the impedance type are back-drivable, have low friction and inertia, and have force-source actuators. A commonly used impedance haptic device in robotics-related research is the Phantom Premium [42.20, 23]. Robots of the admittance type, such as typical industrial robots, are non-back-drivable and have velocity-source actuators. The velocity is controlled with a high-bandwidth low-level controller, and is assumed to be independent of applied external forces. Some commercially available haptic devices, such as the HapticMaster [42.24], do operate under admittance control. While such closed-loop force control has been used for haptic display, more commonly designers have opted for mechanisms specially designed for open-loop force control to achieve simultaneously low cost and high bandwidth.

The choice of admittance or impedance architecture has many profound implications in the design of the software and hardware system. For a variety of reasons, including cost, the majority of haptic devices implemented today are of the impedance type. Because the preponderance of systems today are impedance devices and limitations on space, we limit our subsequent discussion to that class.

42.2.1 Mechanisms

Creating high-fidelity haptic sensations in the operator requires attention to mechanism design (Chap. 5). The

requirements for impedance haptic devices are similar to those for designing manipulators suitable for force control. Desirable mechanism attributes for open-loop force control include low inertia, high stiffness, and good kinematic conditioning throughout a workspace designed to effectively match the appropriate human limb, primarily the finger or arm. The weight of the mechanism should be minimized, as it is perceived by the operator as weight and inertia of the virtual or teleoperated environment. Kinematic singularities (Chaps. 2, 5, and 18) are detrimental to haptic interfaces because they create directions in space in which the end-point cannot be moved by the human operator and thus impose disturbances on the illusion of haptic contact with virtual objects. High transmission ratios must be avoided as they introduce significant amounts of friction. This constraint requires haptic interfaces to make high demands on actuator performance.

Measures of Mechanism Performance

The ideal haptic device can move freely in any direction and is free of singular configurations as well as the *bad* effects of operating in their neighborhood. Traditionally, kinematic performance has been derived from the mechanism's Jacobian matrix, $\mathbf{J}(p, q)$, using some of the following well-known measures:

- Manipulability [42.25]: the product of the singular values of $\mathbf{J}(p, q)$
- Mechanism isotropy [42.26]: the ratio of smallest to the largest singular value of $\mathbf{J}(p, q)$
- Minimum force output [42.25, 27, 28]: maximizing the force output in the *worst* direction.

Dynamics can also be introduced into the cost function using measures such as dynamic manipulability [42.29]. This is still an active area of research and

there is no consensus yet on which dexterity measure is most appropriate for haptic devices.

Kinematic and Dynamic Optimization

This aspect of design requires synthesis of mechanisms that match the workspace of the (most often) human finger or arm while simultaneously avoiding kinematic singularities.

A haptic device workspace is defined to match that of the targeted human limb. This can be assisted by the use of anthropometric data [42.30]. The performance goals, such as low inertia and avoidance of kinematic singularities, must be formalized into a quantitative performance measure which can be computed for any candidate design. Such a measure must account for:

- Uniformity of kinematic conditioning throughout the target workspace
- Favoring designs with lower inertia
- Guaranteeing that the target workspace is reachable.

The measures of mechanism performance defined above operate at a single point in space and thus must be integrated over the entire workspace to derive a figure of merit for a proposed haptic device design. For example, if S is the set of all joint angles Θ , such that the end effector is inside the target workspace, one such measure is

$$M = \min_S W(\Theta), \quad (42.1)$$

where $W(\Theta)$ is a measure of design performance. The performance measure should include a link length penalty such as

$$M = \min_S \frac{W(\Theta)}{l^3}, \quad (42.2)$$

in order to avoid solutions which have excessive size, compliance, and mass of long links. We could search a large family of mechanism designs to maximize M . For example, if a design has five free parameters (typically link lengths and offsets), and we study ten possible values for each parameter, 10^5 designs must be evaluated.

Available computing power has grown much faster than the complexity of realizable mechanisms on the human scale (as measured by their DOF). Thus, brute-force search of design spaces is often sufficient, and sophisticated optimization techniques are not necessary.

Grounded Versus Ungrounded Devices

Most current devices that provide kinesthetic feedback are physically grounded, that is, forces felt by the operator are with respect to the operator's *ground*, such as the

floor or desktop. Ungrounded haptic feedback devices are more mobile and can operate over larger workspaces compared to grounded devices, which enables them to be used in large-scale virtual environments. A number of ungrounded kinesthetic feedback devices have been developed, for example [42.31–33]. Comparisons have been made between the performance of ungrounded and grounded haptic displays [42.34]. Some ungrounded devices provide tactile rather than kinesthetic sensations, and these are described in Sect. 42.5.

42.2.2 Sensing

Haptic devices require sensors to measure the state of the device. This state may be modified by the operator's applied position/force, the haptic control law, and/or device and environment dynamics. The operator's input is sensed in the form of an applied position or an applied force. Sensing requirements for haptics are similar to those of other robotic devices (Chap. 29) so only haptics-specific sensing issues are discussed here.

Encoders

Rotary optical quadrature encoders are typically used as position sensors on the joints of haptic devices. They are often integrated with rotary motors, which serve as actuators. The underlying sensing mechanism for encoders is described in Sect. 29.1. The required resolution of an encoder for a haptic device depends on the ratio between the angular distance of a single encoder tick to the end-point motion in Cartesian space. The resolution of the selected position encoder has effects beyond simple spatial resolution of the end-point, including the maximum stiffness that can be rendered (Sect. 42.4) without unstable or nonpassive behavior [42.35].

Many haptic applications, such as the rendering of virtual environments with damping (in which force is proportional to velocity), require velocity measurement. Velocity is typically obtained by numerical differentiation of the position signal obtained by an encoder. An algorithm for velocity estimation must be selected which is free of noise but minimizes phase lag at the frequencies of interest [42.36]. Thus, an alternative method is to use specialized hardware that measures the time between encoder ticks in order to compute the velocity [42.37].

Force Sensors

Force sensors are used in haptic devices as the operator input to an admittance-controlled device, or as a mechanism for canceling device friction and other undesirable dynamic properties in an impedance-controlled device.

When a force sensor such as a strain gauge or load cell measures the operator's applied force, care must be taken to thermally isolate the sensor, since thermal gradients in the sensor caused by body heat can affect force readings.

42.2.3 Actuation and Transmission

Haptic devices are differentiated from traditional computer input devices by actuators that are controlled to provide appropriate haptic sensations to the human operator. The performance of the haptic device depends heavily on the actuator properties and the mechanical transmission between the actuator and the haptic interaction point (HIP).

Requirements for Haptics

The primary requirements for actuators and mechanical transmission in impedance-type haptic devices are: low inertia, low friction, low torque ripple, back-driveability, and low backlash. In addition, if the design is such that the actuator itself moves as the user's position changes, a higher power-to-weight ratio is desired. Although closed-loop force control has been used for haptic display in impedance devices, most often the mechanism is designed to have sufficiently low friction and inertia so that open-loop force control is accurate enough.

One common mechanical transmission for haptic devices is the capstan drive (Fig. 42.6), which consists of smooth cables wrapped around pulleys of differing diameter to provide a gear ratio. A no-slip, high-friction contact between the cable and the pulleys is maintained through several wraps of the cable. The capstan drive

minimizes friction forces felt by the human operator because it prevents translational forces on motor and joint axes.

Current amplifiers are typically used to create a direct relationship between the voltage output by the computer via a digital-to-analog (D/A) converter and the torque output by the motor. The effect of actuator and amplifier dynamics and D/A resolution on system stability is typically negligible in comparison to position sensor resolution and sampling rate for most haptic devices. Actuator or amplifier saturation can produce undesirable behavior, particularly in multi-DOF haptic devices where a single saturated motor torque may change the apparent geometry of virtual objects. The force vector, and thus the corresponding actuator torques, must be scaled appropriately if any actuator is saturated.

42.2.4 An Example Device

As an illustrative example, we will provide detailed design information for a simple 1-DOF haptic device known as the Haptic Paddle [42.38]. This section is meant to provide a concrete description of the types of components that are used in kinesthetic haptic devices, and the device can also be constructed following the instructions provided by Johns Hopkins University. Many widely available haptic devices share the common working principles of this device and differ chiefly in kinematic details arising from a greater number of DOF.

The haptic paddle shown in Fig. 42.6 is equipped with two sensors: a position encoder and a force sensor. A 500-counts-per-turn Hewlett-Packard HEDS 5540 encoder that is mounted directly on the motor. The quadrature process yields 2000 counts per revolution; the capstan transmission gear ratio and lever arm result in a position resolution of 2.24×10^{-5} m at the haptic interaction point (HIP). An optional load cell is used to measure the applied operator force. A plastic cap thermally insulates the load cell. In this device, the load cell can be used to minimize the effect of friction through a control law that attempts to zero the applied operator force when the HIP is not in contact with a virtual object.

The Haptic Paddle shown uses a brushed DC (direct current) motor with an aluminum pulley attached to the shaft. Like many commercial haptic devices, it uses a capstan drive: a cable is wrapped several times around the motor pulley and attached at each end of the large partial pulley. In one instantiation, the output of the digital-to-analog (D/A) converter from the microprocessor is passed through a current amplifier that gives a current through the motor that is proportional

Fig. 42.6 This version of the Haptic Paddle [42.38] includes an encoder for position sensing, a single-axis load cell for force sensing, and a brushed motor with capstan transmission for actuation

to the D/A voltage. This gives direct control of applied torque on the motor. The resulting system has a force felt at the driving point that is proportional to the out-

put voltage during static operation. When the system is moving, the force applied to the operator may differ due to human and device dynamics.

42.3 Haptic Rendering

Haptic rendering (in impedance systems) is the process of computing the force required by contacts with virtual objects based on measurements of the operator's motion. This section describes haptic rendering for virtual environments. Haptic feedback for teleoperators is described in Chap. 43.

An important property of haptic systems is that their timing constraints are quite severe. To illustrate this point, tap a pencil on the table top. You hear a sound which is an audio representation of the contact dynamics between pencil tip and table top. Tactile receptors in the human fingers are known to respond up to 10 kHz [42.1]. To realistically render this type of contact between hard surfaces would require response well into the audio range of frequencies (up to 20 kHz) and thus sampling times of around 25 μ s. Even with specialized designs, haptic devices do not have this bandwidth, and such high fidelity is not usually a goal of haptic rendering. Achieving stability in any type of hard contact requires very high sampling rates. In practice, most haptic simulation systems are implemented with at least 1000 Hz sampling rate. This can be reduced to the low hundreds of Hertz if the virtual environment is limited to soft materials.

Basic Haptic Rendering

The computational process of haptic rendering can be formulated into the following seven sequential steps for each cycle (Fig. 42.7). The rendering cycle must typically be completed in under 1 ms for stability and realism:

1. Sensing (Sect. 42.2.2)
2. Kinematics
3. Collision detection
4. Determining surface point
5. Force calculation
6. Kinematics
7. Actuation (Sect. 42.2.3).

Kinematics

The position and velocity measurements acquired by sensors are typically in joint space. These must be converted through the forward kinematics model and the Jacobian matrix (Chap. 2) to the Cartesian position and velocity of the operator's hand or fingertip. In some

applications the operator is virtually holding a tool or object whose shape is represented in the virtual environment but whose position and orientation are determined by the operator. In those others, the operator's fingertip or hand is represented by a point which makes only point contact with objects in the virtual environment (VE). We refer to a virtual handheld object as a virtual tool and, following [42.39], we refer to the single end-point as the haptic interaction point (HIP).

Collision Detection

For the point contact case, the collision detection software must determine if the position of the HIP at the current instant of time represents contact with a virtual object. In practice this usually means to determine if the HIP is penetrating or inside the object surface. The object surface is represented by a geometric model such as polygons or splines.

Although there is an extensive literature on collision detection in computer graphics, there are unique aspects of the collision detection problem for haptics. In particular, speed of computation is paramount and worst-case speed, as opposed to average speed, is what counts. Solutions that evaluate in constant time are pre-

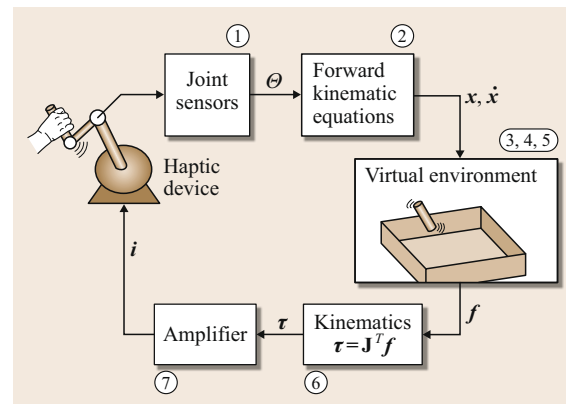

Fig. 42.7 Schematic diagram of the haptic rendering cycle for an impedance haptic display system. Virtual object moves in the virtual environment according to operator's displacement of the haptic device. Joint displacements (θ) sensed in the device (1) are processed through kinematics (2), collision detection (3), surface point determination (4), force calculation (5), kinematics (6), and actuation (7)

ferred. Section 42.3.1 addresses collision detection and haptic rendering for complex environments.

If the HIP is found to be outside all objects, then a force of zero is returned.

Determining Surface Point

Once it is determined that the HIP is inside a surface, the force to be displayed to the operator must be computed. Many researchers have used the idea of a virtual spring connecting the HIP to the nearest point on the surface as a model of interpenetration and force generation [42.39–41]. Basdogan and Srinivasan named this point the intermediate haptic interaction point (IHIP). However all of these authors realized that the closest surface point is not always the most faithful model of contact. For example, as the HIP moves laterally below the top surface of a cube (Fig. 42.8), eventually it becomes close enough to the edge that the closest surface point becomes the side of the cube. In this situation, the algorithm needs *memory* to keep the IHIP on the top surface and generate an upward force at all times or the operator is suddenly ejected out the side of the cube.

Force Calculation

Force is commonly computed by using the spring model (Hooke's Law)

$$\mathbf{f} = k\mathbf{x}, \quad (42.3)$$

where \mathbf{x} is the vector from the HIP to the IHIP, and $k > 0$. When k is sufficiently large, the object surface will feel like a wall perpendicular to \mathbf{x} . This *virtual wall*, or impedance surface, is a fundamental building block

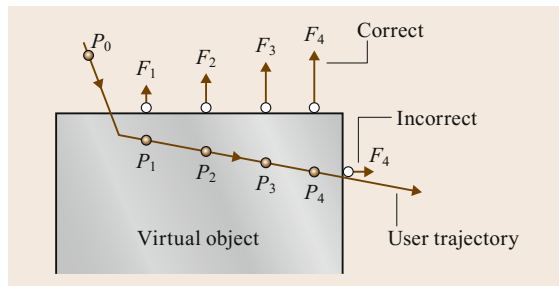

Fig. 42.8 Illustration of subtle aspects of haptic rendering of contact force. The operator fingertip trajectory enters object surface moving down and to the right. Haptic interaction points (HIP) are shown at times 1–4 (solid circles, P_0 – P_4). Intermediate haptic interaction points (IHIP) are shown when the HIP is inside the object (open circles). At position P_4 , the algorithm must not render force based on the closest surface point or the operator will be ejected from the side of the object (feeling unnatural force tangential to the top surface)

of most haptic virtual environments. Because the virtual wall is only displayed if a collision between the HIP and virtual object is detected, the wall is a unilateral constraint, governed by a nonlinear switching condition. As will be described in the following section, haptic virtual environments with complex geometries are often formed using a polygonal mesh in which each polygon is essentially a virtual wall. A virtual surface may also be allowed to deform globally, while the local interaction with the operator is governed by a virtual wall. *Virtual fixtures*, which are often constructed from virtual walls, can be overlaid on haptic feedback teleoperators to assist the operator during a teleoperated task (Chap. 43).

The pure stiffness model described above can be augmented to provide other effects, particularly through the use of the *virtual coupling* described in Sect. 42.3.2. Damping can be added perpendicular or parallel to the surface. In addition, Coulomb or other nonlinear friction may be displayed parallel to the surface. To provide a more realistic display of hard surfaces, vibrations can also be displayed open loop at the moment of collision between the HIP and the surface, as is described in Sect. 42.5.

Kinematics

The computed force in Cartesian space must then be transformed into torques in the actuator space. Typically the calculation is

$$\boldsymbol{\tau} = \mathbf{J}^T \mathbf{f}, \quad (42.4)$$

where $\boldsymbol{\tau}$ is the torque command to the actuators, \mathbf{f} is the desired force vector, and \mathbf{J}^T is the transpose of the haptic device Jacobian matrix (Chap. 2). If the haptic device has no dynamics and the actuators are perfect, the exact desired force is displayed to the operator. However, real device dynamics, time delays, and other nonidealities result in applied operator forces that differ from the desired forces.

42.3.1 Rendering Complex Environments

Today's computer power is sufficient that a variety of relatively simple algorithms can effectively render haptics for simple virtual environments, say consisting of a handful of simple geometric primitives such as spheres, cubes, and planes. However, the challenge is to scale these algorithms to complex environments such as those we are used to seeing in computer graphic renderings consisting of 10^5 – 10^7 polygons. A variety of approaches have been tried in the literature for efficient rendering of complex scenes. Zilles and Salisbury [42.40] found planar constraints due to

the nearby surface polygons and solved for the closest **IHIP** point using Lagrange multipliers. *Ruspini* and *Khatib* [42.42] added force shading and friction models. *Ho* et al. [42.39] used a hierarchy of bounding spheres to determine the initial contact (collision) point, but thereafter searched neighboring surfaces, edges, and vertices (referred to as geometric primitives) of the current contacted triangle to find the closest point for the **IHIP**. *Gregory* et al. [42.43] imposed a discretization of three-dimensional (**3-D**) space onto the hierarchy to speed up the detection of initial contact with the surface. *Johnson* et al. [42.44] performed haptic rendering on moving models based on local extrema in distance between the model controlled by the haptic device and the rest of the scene. *Lin* and *Otaduy* [42.45, 46] used level-of-detail representations of the objects for performing multiresolution collision detection, with the goal of satisfying real-time constraints while maximizing the accuracy of the computed proximity information.

Alternative algorithms and efficiencies can be derived by not representing the object surface as polygons. *Thompson* and *Cohen* [42.47] derived the mathematics for computing the interpenetration depth for surfaces directly from non-uniform rational B-spline (**NURBS**) models. *McNeely* et al. [42.18] took the extreme approach of voxelizing space at the millimeter scale. Each voxel contained a precomputed normal vector, stiffness properties, etc. 1000 Hz rendering was achieved with very complex **CAD** models containing millions of polygons (in the graphical equivalent representation), but large amounts of memory and precomputation are required. The performance of this algorithm is sufficiently high that it can be used to render hundreds of contact points simultaneously. This allows the operator to hold an arbitrarily shaped tool or object. The tool/object is populated by points surrounding its surface and the resultant force and moment on the tool is the sum of interaction forces computed on all of the surface points.

For surgical simulation, researchers have focused on the modeling and haptic rendering of the interaction between surgical instruments and organs. Researchers have attempted to model virtual tissue behavior in

a wide variety of ways, which can be broadly classified as:

1. Linear elasticity based
2. Nonlinear (hyperelastic) elasticity-based finite-element (**FE**) methods
3. Other techniques that are not based on **FE** methods or continuum mechanics.

While most conventional linear and nonlinear **FE** algorithms cannot be run in real time, methods such as preprocessing can allow them to run at haptic rates [42.48]. Many researchers rely on data acquired from real tissues to model organ deformation and fracture accurately. Major challenges in this field include the modeling of connective tissue supporting the organ, friction between instruments and tissues, and topological changes occurring during invasive surgical procedures.

42.3.2 Virtual Coupling

So far we have rendered forces by computing the length and direction of a virtual spring and applying Hooke's Law (42.3). This spring is a special case of a *virtual coupling* [42.41] between the **HIP** and the **IHIP**. The virtual coupling is an abstraction of the interpenetration model of force rendering. Instead of viewing the objects as compliant, we assume them to be rigid but connect them to the operator through a virtual spring. This imposes an effective maximum stiffness (that of the virtual coupling).

Problems with stable contact rendering (Sect. 42.4) often require more sophisticated virtual couplings than a simple spring. For example, damping can be added, generalizing the force rendering model of (42.3) to

$$f = kx + b\dot{x} . \quad (42.5)$$

The parameters k and b can be empirically tuned for stable and high-performance operation. More-formal design methods for the virtual coupling are covered in Sect. 42.4.

42.4 Control and Stability of Force Feedback Interfaces

Introduction to the Problem

The haptic rendering system depicted in Fig. 42.7 is a closed-loop dynamical system. It is a challenge to render realistic contact forces yet retain the stable behavior of human-environment contact in the natural world. Instability in haptic interfaces manifests itself as buzzing, bouncing, or even wildly divergent behavior. The worst

case for impedance devices is during attempted contact with stiff objects. Empirically, instability is frequently encountered when developing haptic interfaces with stiff virtual objects, but this instability can be eliminated by reducing the stiffness of the virtual object or by the operator making a firmer grasp on the haptic device.

Problem Description in Classical Control Terms

Although linear theory is of very limited use in haptic control applications, it can be applied to a basic analysis of the factors affecting instability [42.49]. Such a highly simplified model of an impedance device is shown in Fig. 42.9. $G_1(s)$ and $G_2(s)$ represent dynamics of the haptic device for both operator position sensing and force display respectively. Assume that the virtual environment and human operator/user (HO) can each be represented by a linear impedance such as

$$Z_{VE} = \frac{F_{VE}(s)}{X_{VE}(s)}, \quad (42.6)$$

$$Z_{HO} = \frac{F_{HO}(s)}{X_{HO}(s)}. \quad (42.7)$$

Then the loop gain of the closed-loop system from the human operator and back again is

$$G_I(s) = G_1(s)G_2(s) \frac{Z_{VE}(s)}{Z_{HO}(s)}. \quad (42.8)$$

Stability in the classical sense is assessed by applying the magnitude and phase criteria of Nyquist to $G_I(s)$. Increasing Z_{VE} (corresponding to stiffer or heavier virtual objects) increases the magnitude of $G_I(s)$ and thus destabilizes the system while a firmer grasp by the human operator, which increases the magnitude of Z_{HO} , has a stabilizing effect. Similar arguments apply to phase shifts that might be present in any part of the system.

Limitations of Linear Theory

Although the model of Fig. 42.9 illustrates some qualitative features of haptic interface stability, linear continuous time theory is of little use in designing methods to stabilize the loop. Interesting virtual environments are nonlinear. Furthermore, they can rarely be linearized because applications often simulate discontinuous contact, for example, between a stylus in free space and a hard surface. A second feature is digital implementation, which introduces sampling and quantization – both of which have significant effects.

Fig. 42.9 Highly simplified linear model of haptic rendering to highlight some stability issues

Sampling

Colgate et al. [42.41] incorporated consideration of discrete time sampling behavior in the stability analysis. They considered the problem of implementing a virtual wall of stiffness

$$H(z) = K + B \frac{z-1}{Tz}, \quad (42.9)$$

where K is the virtual wall stiffness, B is the virtual wall damping coefficient, z is the z -transform variable, and T is the sampling time. They further modeled the haptic device (HD) in continuous time as

$$Z_{HD}(s) = \frac{1}{ms + b}, \quad (42.10)$$

where m and b are the mass and damping of the haptic device, respectively. They derived the following condition for passivity of the device

$$b > \frac{KT}{2} + |B|, \quad (42.11)$$

showing a significant stabilizing effect of high sampling rates and also of high mechanical damping in the haptic device.

Quantization

Additional factors include delays due to numerical integration schemes and quantization. These contributing factors to instability have been termed *energy leaks* by Gillespie and Cutkosky [42.50].

Passivity

Interesting virtual environments are always nonlinear and the dynamic properties of a human operator are important. These factors make it difficult to analyze haptic systems in terms of known parameters and linear control theory. One fruitful approach is to use the idea of passivity to guarantee stable operation. Passivity is a sufficient condition for stability, and is reviewed more completely in Chap. 43 on telerobotics. There are many similarities between the control of haptic interfaces and bilateral teleoperation.

The major problem with using passivity for design of haptic interaction systems is that it is overly conservative, as shown in [42.35]. In many cases, performance can be poor if a fixed damping value is used to guarantee passivity under all operating conditions. Adams and Hannaford derived a method of virtual coupling design from two-port network theory which applied to all causality combinations and was less conservative than passivity based design [42.51]. They were able to derive optimal virtual coupling parameters using a dynamic model of the haptic device and by satisfying Lewellyn's *absolute stability criterion*, an inequality

composed of terms in the two-port description of the combined haptic interface and virtual coupling system. *Miller et al.* derived another design procedure which

extended the analysis to nonlinear environments and extracted a damping parameter to guarantee stable operation [42.52–54].

42.5 Other Types of Haptic Interfaces

While kinesthetic (force feedback) haptic interfaces have the closest relationship to robotics, there are a variety of other types of haptic interfaces which are usually classified as tactile displays. Tactile displays are used to convey force, contact and shape information to the skin. They purposely stimulate cutaneous receptors, with little effect on kinesthetic sensation. This is in contrast to kinesthetic displays, which must inherently provide some cutaneous sensations through physical contact with a tool or thimble, but whose primary output is force or displacement to the limbs and joints. Tactile displays are usually developed for a specific purpose, such as display of contact events, contact location, slip/shear, texture, and local shape. Special purpose tactile displays can be targeted at different types of cutaneous receptors, each with its own frequency response, receptive field, spatial distribution, and sensed parameter (e.g., local skin curvature, skin stretch, and vibration) and each receptor type is associated with different exploratory procedures described in Sect. 42.1.1.

In contrast, tactile displays that render contact information for virtual reality or teleoperation have proven far more challenging. Accurate recreation of the local shape and pressure distribution at each fingertip requires a dense array of actuators. Devices specifically aimed at tactile perception are an active area of research but most have not reached the stage of applications or commercial distribution, with the notable exception of Braille displays for the blind. In this section, we describe the various types of tactile displays, their design considerations and specialized rendering algorithms, and applications.

42.5.1 Vibrotactile Feedback

Vibrotactile feedback is a popular method of providing tactile feedback. It can be used as a stand-alone method for haptic feedback or as an addition to a kinesthetic display. Vibrating elements, such as piezoelectric materials and small voice-coil motors, are lighter than the actuators used in kinesthetic devices, and can often be added to kinesthetic devices with little impact on existing mechanisms. In addition, high-bandwidth kinesthetic displays can be programmed to display open-loop vibrations through their normal actuators. The sensitivity

for human vibration sensing ranges from DC to over 1 kHz, with peak sensitivity around 250 Hz.

We first consider the use of vibrations to convey impact or contact events – a technique that straddles kinesthetic and tactile feedback. When humans touch an environment, fast-acting sensors embedded in the skin record the minute vibrations occurring from this interaction. As described in Sect. 42.3, conventional approaches to haptic display usually consist of designing a virtual model with simple geometry, then using a first-order stiffness control law to emulate a surface. However, such first-order models often lack the realism of higher-order effects such as impact. With common haptic rendering algorithms, surfaces feel squishy or unrealistically smooth. One solution to improving the realism of such environments is to add higher-order effects such as textures and contact vibrations. These effects can use a library of surface models based on ad hoc analytical descriptions [42.55], which are sometimes tuned using qualitative operator feedback, physical measurements (reality-based models created from empirical data) [42.56, 57], or a combination of the two [42.58]. At the instant collision is detected between the HIP and a surface of the virtual object, the appropriate waveform is called out of the library, scaled according to the context of the motion (such as velocity or acceleration), and played open loop through an actuator. That actuator may be the same one simultaneously displaying lower-frequency force information, as shown in Fig. 42.10, or it might be a separate transducer. *Kuchenbecker et al.* [42.59] considered the dynamics of the haptic device to display the most accurate vibration waveforms possible, and compared a number of different vibration waveform generation techniques meant to convey impact superimposed on force feedback in virtual environments. Most of the vibration feedback methods performed similarly in terms of realism, and they were also significantly more realistic than conventional force feedback alone.

Vibration feedback can also be used to provide information about patterned textures, roughness, and other phenomena that have clear vibratory signals. This type of vibration feedback is often termed *vibrotactile* feedback. In teleoperated environments, *Kontarinis and Howe* [42.60] showed that damaged ball bear-

ings could be identified through vibration feedback, and Dennerlein et al. [42.61] demonstrated that vibration feedback improved performance over no haptic feedback, for a telemanipulation task inspired by undersea field robotics. In these teleoperator systems, vibration-sensitive sensors such as accelerometers and piezoelectric sensors are used to pick up and, in most cases, directly provide the vibration signals as inputs to a vibrotactile actuator. In virtual environments, Okamura et al. [42.62] displayed vibrations modeled based on textures and puncture of a membrane. Similar to the event-based haptics above, the vibration waveforms were modeled based on earlier experiments and played open loop during interaction with the virtual environment.

Finally, vibration feedback has been used as a method of sensory substitution, to convey direction, attention, or other information, e.g., [42.63–65]. In this case, the strength and clarity of the signal, not realism, is the goal. Vibration frequencies near the peak human sensitivity are most effective, and there exist commercially available vibrotactile actuators (or *tactors*) suitable for such applications, e.g., Engineering Acoustic, Inc.'s C2 Tactor [42.66]. Elements within an array of tactors can be selectively turned on and off to evoke the sensory saltation phenomenon, in which a pattern of brief pulses on a series of tactors is perceived not as successive taps at different locations, but as a single tap that is traveling or hopping over the skin.

Fig. 42.10 Event-triggered open-loop force signals superimpose on traditional penetration-based feedback forces, providing vibration feedback that improves the realism of hard surfaces in virtual environments (after [42.59] with permission)

42.5.2 Contact Location, Slip, and Shear Display

In early work related to robotic dexterous manipulation, it was found that knowledge of the contact point between a robot hand and a grasped object is essential for manipulation. Without this knowledge, the robot will easily drop the object due to rapid accumulation of grasp errors. While many robotics researchers and some companies have developed tactile array sensors capable of measuring contact location, pressure distribution, and local object geometry (Chap. 28), practical methods for display of this information to the human operator of a virtual or teleoperated environment have proven much more difficult. We begin our discussion of contact display by considering contact location, slip, and shear display, which have the common goal of displaying the motion of a single area of contact relative to the skin (almost invariably on a finger). Arrays of pins that rise and fall to create a pressure distribution on the skin have been the most popular method to date for displaying contact information, but we will address those designs in the following section on local shape, since their primary advantage is the display of spatially distributed information. Instead, we will focus here on tactile devices that are designed to specifically address the problem of contact location and motion.

As an example of contact location display, Provancher et al. [42.67] developed a system that renders the location of the contact centroid moving on the user's fingertip. The tactile element is a free-rolling cylinder that is normally suspended away from the fingertip, but comes into contact with the skin when the operator pushes on a virtual object. The motion of the cylinder over the skin is controlled by sheathed push-pull wires. This allows the actuators to be placed remotely, creating a lightweight, thimble-sized package that can be unobtrusively mounted on a kinesthetic haptic device. An experiment demonstrated that human operators performed similarly during real manipulation and virtual manipulation (using the tactile display) in an object curvature discrimination task. In addition, operators were able to use the device to distinguish between manipulations of rolling and anchored but rotating virtual objects.

42.5.3 Slip and Shear

Humans use slip and incipient slip widely during manipulation tasks [42.68]. To reproduce these sensations for experiments to characterize human slip sensation, researchers have created stand-alone 1-DOF slip displays [42.69–71]. Webster et al. [42.71] created a 2-DOF tactile slip display, which uses an actuated ro-

tating ball positioned under the user's fingertip. The lightweight, modular tactile display can be attached to a multi-DOF kinesthetic interface and used to display virtual environments with slip. Experimental results demonstrate that operators complete a virtual manipulation task with lower applied forces using combined slip and force feedback in comparison with conventional force feedback alone. Skin stretch can also be integrated with a slip display to provide information about pre-slip conditions. For example, *Tsagarakis et al.* [42.72] developed a lightweight device that uses a V configuration of miniature motors to provide sensations of relative lateral motion (direction and velocity) onto the operator's fingertips. Generation of two-dimensional (2-D) slip/stretch is achieved by coordinating the rotational speed and direction of the two motors.

In terms of tactile device kinematics, slip and shear displays can be quite similar. However, the goal of shear, or skin stretch, displays is to maintain a no-slip condition such that shear forces/motions can be accurately controlled with respect to the human operator, typically on the finger. The use of shear (tangential skin stretch) is motivated by perceptual experiments demonstrating that the human fingerpad is more sensitive to tangential displacement compared to normal displacement [42.73]. A variety of tangential skin stretch devices have been designed, with applications in wearable haptics, high-fidelity tactile rendering, and teleoperation. *Hayward and Cruz-Hernandez* [42.74] developed a tactile device consisting of closely packed piezoelectric actuators, which generates a programmable stress field within the fingerpad. Single skin-stretch *tactors* have also been used to convey two-dimensional directional information (for navigation) [42.75] and to enhance perception of virtual environments (e.g., friction) [42.76] alone or in combination with kinesthetic haptic interfaces. A similar approach has been used for 3-DOF skin stretch, in combination with cutaneous normal force [42.77, 78]. In a different form factor, researchers have developed rotational skin stretch devices that can act as a substitute for natural proprioceptive feedback [42.79, 80].

42.5.4 Local Shape

Most tactile devices for local shape display consist of an array of individual pin elements that move normal to the surface. Often, a layer of elastic material is used to cover the pins so that the operator contacts a smooth surface rather than the pins directly. Other systems use individual elements that move laterally, and some substitute electrodes for moving parts to form an array of electrocutaneous elements. A number of researchers have used psychophysical and percep-

tual experimental results to define design parameters such as number of pins, spacing, and amplitude of pin-based tactile displays. A commonly used metric is the two-point discrimination test, which defines the minimum distance between two contact points on the skin at which they are perceived as two, rather than one point. This discrimination limit varies widely for skin on different parts of the body, with the fingertips having one of the smallest (usually cited as less than 1 mm, although this depends on the shape and size of the contacts) [42.81, 82]. *Moy et al.* [42.83] quantified several perceptual capabilities of the human tactile system based on predicted subsurface strain and psychophysical experiments that measured amplitude resolution, the effects of shear stress, and the effects of viscoelasticity (creep and relaxation) on tactile perception for static touch. They found that 10% amplitude resolution is sufficient for a teletaction system with a 2 mm elastic layer and 2 mm *tactor* spacing. A different type of experiment examines the kind of tactile information relevant to a particular application. For example, *Peine and Howe* [42.84] found that sensed deformation of the fingerpad, and not changes in pressure distribution, were responsible for localizing lumps in a soft material, such as a tumor in tissue.

We will now highlight a few distinctive designs of array-type tactile displays. A number of actuator technologies have been applied to create tactile arrays, including piezoelectric, shape-memory alloy (SMA), electromagnetic, pneumatic, electrorheological, micro-electromechanical system (MEMS), and electrotactile. Further reading on tactile display design and actuation is available in review papers, including [42.85–90].

We will first consider two ends of the spectrum in complexity/cost of the pin-based approach. *Killebrew et al.* [42.91] developed a 400-pin, 1 cm² tactile stimulator to present arbitrary spatiotemporal stimuli to the skin for neuroscience experiments. Each pin is under independent computer control and can present over 1200 stimuli per minute. While not practical for most haptic applications due to the size and weight of the actuation unit, it is the highest-resolution tactile display built to date and can be used to evaluate potential designs for lower-resolution displays. *Wagner et al.* [42.92] created a 36-pin, 1 cm² tactile shape display that uses commercially available radio-controlled (RC) servomotors. The display can represent maximum frequencies of 7.5–25 Hz, pending on the amount of pin deflection, and is shown in Fig. 42.11. *Howe et al.* [42.93, 94] have also explored the use of shape-memory alloys for pin actuation, for the application of remote palpation.

In contrast to pins that move normal to the surface, recent tactile array designs have incorporated

pins that move laterally. First introduced by *Hayward* and *Cruz-Hernandez* [42.95], the most recent compact, lightweight, modular design [42.96] uses a 6×10 piezo bimorph actuator array with a spatial resolution of $1.8 \text{ mm} \times 1.2 \text{ mm}$. The force of the individual actuators provides sufficient skin pad motion/stretch to excite mechanoreceptors [42.97]. A pilot test demonstrated that subjects could detect a virtual line randomly located on an otherwise smooth virtual surface, and the device has also been tested as a Braille display [42.98]. Another lateral stretch display and its evaluation is described in [42.99]. Other novel approaches to tactile display include sending small currents through the skin or tongue using an electrocutaneous array [42.100] and the application of air pressure to stimulate only superficial mechanoreceptors [42.101].

42.5.5 Surface Displays

In recent years, the concept of surface displays, which modulate surface friction in order to display changing shear forces as a user moves the finger over the surface. One example device that uses slip and friction to display compelling tactile sensations is the **TPaD**

(tactile pattern display) [42.102]. Ultrasonic frequency, low amplitude vibrations of a flat plate create a film of air between the plate and a human finger touching the plate, thereby reducing friction. The 33 kHz vibration of the plate cannot be perceived by the human. The amount of friction reduction varies with vibration amplitude, allowing indirect control of shear forces on the finger during active exploration. Finger position and velocity feedback enables haptic rendering of spatial texture sensations. This work has been expanded into a variety of different surface displays, including devices that generate active forces [42.103] and those that use electrostatic forces to modulate friction [42.104, 105].

42.5.6 Temperature

Because the human body is typically warmer than objects in the environment, thermal perceptions are based on a combination of thermal conductivity, thermal capacity, and temperature. This allows us to infer not only temperature difference, but also material composition [42.106]. Most thermal display devices are based on thermoelectric coolers, also known as Peltier heat pumps. Thermoelectric coolers consist of a series of semiconductor junctions connected electrically in series and thermally in parallel. The thermoelectric cooler is designed to pump heat from one ceramic faceplate to the other, but if used in reverse, a temperature gradient across the device produces a proportional potential; as a measure of relative temperature change. The designs of haptic thermal displays mostly use off-the-shelf components, and their applications are typically straightforward, enabling identification of objects in a virtual or teleoperated environment by their temperature and thermal conductivity.

Ho and *Jones* [42.107] provide a review of haptic temperature display, as well as promising results suggesting that a thermal display is capable of facilitating object recognition when visual cues are limited. Although numerous systems have integrated thermal display with other types of haptic display, the Data Glove Input System designed by *Caldwell* et al. [42.108, 109] was one of the first to do so. Their haptic interface provides simultaneous force, tactile, and thermal feedback. The Peltier device used for thermal display contacts the dorsal surface of the index finger. Subjects achieved a 90% success rate in identifying materials such as a cube of ice, a soldering iron, insulating foam, and a block of aluminum, based only on thermal cues. The study of human temperature perception is particularly interesting, including issues such as spatial summation and the psychological relevance of temperature display. For example, in prosthetic limbs, temperature display

Fig. 42.11 (a) A low-cost 36-pin tactile display using RC servomotor actuation. (b) A closeup of the 6×6 display, showing a sine wave grating (after [42.92] with permission)

may be useful not only for practical reasons such as safety and material identification, but also for reasons of

personal comfort, such as feeling the warmth of a loved one's hand.

42.6 Conclusions and Further Reading

Haptic technology, which attempts to provide compelling sensations to human operators in virtual and teleoperated environments, is a relatively new, but fast-growing and dynamic area of research. The field relies not only on fundamental foundations from robotics and control theory, but also on fields in the human sciences, particularly neuroscience and psychology. To date, commercial success of haptics has been in the areas of entertainment, medical simulation, and design, although novel devices and applications are regularly appearing.

There exist many books on the topic of haptic technology, most of them compendiums from workshops or conferences on the subject. One of the earliest books on haptics, by Burdea [42.110], provides a thorough review of applications and haptic devices up to 1996. A book specifically focused on haptic rendering, designed for potential use as a textbook, has been edited by Lin and Otaduy [42.111]. In addition, we recommend the following useful articles: Hayward and MacLean [42.112, 113] describe the fundamentals of constructing experimental haptic devices of modest

complexity, the software components needed to drive them, and the interaction design concepts important to creating usable systems. Hayward et al. [42.114] also provide a tutorial on haptic devices and interfaces. Salisbury et al. [42.115] describe the basic principles of haptic rendering. Hayward and MacLean [42.116] describes a number of tactile illusions that can inspire creative solutions for haptic interface design. Robles-De-La-Torre [42.117] underscores the importance of haptics with compelling examples of humans who have lost the sense of touch.

Finally, there exist two journals that are specific to the field of haptics: *Haptics-e* [42.118] and *IEEE Transactions on Haptics* (first issue expected 2008). Several conferences are specifically devoted to haptics: Eurohaptics and the Symposium on Haptic Interfaces for Virtual Environment and Teleoperator Systems are held separately in even years, and on the odd years become a single conference, World Haptics. The IEEE (Institute of Electrical and Electronics Engineers) technical committee on haptics [42.119] provides information about relevant publication forums.

43. Telerobotics

Günter Niemeyer, Carsten Preusche, Stefano Stramigioli, Dongjun Lee

In this chapter we present an overview of the field of telerobotics with a focus on control aspects. To acknowledge some of the earliest contributions and motivations the field has provided to robotics in general, we begin with a brief historical perspective and discuss some of the challenging applications. Then, after introducing and classifying the various system architectures and control strategies, we emphasize bilateral control and force feedback. This particular area has seen intense research work in the pursuit of telepresence. We also examine some of the emerging efforts, extending telerobotic concepts to unconventional systems and applications. Finally, we suggest some further reading for a closer engagement with the field.

43.1 Overview and Terminology

Telerobotics is perhaps one of the earliest aspects and manifestations of robotics. Literally meaning robotics at a distance, it is generally understood to refer to robotics with a human operator in control or *human-in-the-loop*. Any high-level, planning, or cognitive decisions are made by the human user, while the robot is responsible for their mechanical implementation. In essence, the *brain* is removed or distant from the *body*.

Herein the term *tele*, which is derived from the Greek and means distant, is generalized to imply a barrier between the user and the environment. This barrier is overcome by remote-controlling a robot at the en-

vironment, as indicated in Fig. 43.1. Besides distance, barriers may be imposed by hazardous environments or scaling to very large or small environments. All barriers prevent the user from physically reaching or directly interacting with the environment.

While the physical separation may be very small, with the human operator and the robot sometimes occupying the same room, telerobotic systems are often at least conceptually split into two sites. The *local site* encompasses the human operator and all elements necessary to support the system's connection with the user, which could be joysticks, monitors, keyboards, or other

Fig. 43.1 Overview of a telerobotic system (after [43.1], adapted from [43.2])

input/output devices. The *remote site* contains the robot, supporting sensors and control elements, and the environment to be manipulated.

To support its operation, telerobotics integrates many areas of robotics. At the remote site, to operate the robot and execute the human's commands, the system may control the motion and/or forces of the robot. We refer to Chaps. 7 and 8 for detailed descriptions of these areas. Also, sensors are invaluable (Chap. 5), including force sensors (Chap. 28) and others (Part C). Meanwhile, at the local site information is often displayed haptically (Chap. 41).

A recent addition to telerobotics is the use of computer networks to transmit information between the sites. The ubiquity of network access is allowing remote control from anywhere on demand. Chapter 44 discusses some of these developments, detailing network infrastructure and focusing on visual, often web-based, user interfaces, avoiding the need for specialized mechanical I/O (input/output) devices. Computer networks also allow new multi-lateral telerobotic architectures. For example, multiple users may share a single robot or a single user may control multiple robots (Sect. 43.5.2). Unfortunately, computer networks often see transmission delays and can introduce nondeterministic effects such as variable delay times and data losses. These effects can easily destabilize force feedback loops and require particular countermeasures (Sects. 43.4.4–43.4.6).

We should also point out the relation between telerobotics and human exoskeletons, as described in Chap. 69. Exoskeletons are also controlled by a human operator, leaving all planning and high-level challenges to the user, and their control systems share many aspects with telerobotics. However, the two sites are physically combined in an exoskeleton as the user directly touches and interacts with the robot. In this chapter, we will disallow any such direct mechanical connection.

The inclusion of the human operator makes telerobotics very attractive to handle unknown and unstructured environments. Applications are plentiful (Part F) and range from space robotics (Chap. 55) to dealing with hazardous environments (Chap. 58), from search and rescue situations (Chap. 60), to medical systems (Chap. 63) and rehabilitation (Chap. 64).

Before proceeding, we define some basic terminology. Indeed many other terms are used nearly synonymously with telerobotics, in particular *teleoperation* and *telem Manipulation*. Telerobotics is the most common, emphasizing a human's (remote) control of a robot. Teleoperation stresses the task-level operations, while telem Manipulation highlights object-level manipulation.

Within telerobotics, a spectrum of control architectures is used. *Direct control* or *manual control* falls at one extreme, indicating that the user is controlling the motion of the robot directly and without any automated help. At the other extreme, *supervisory control* implies that user's commands and feedback occur at a very high level and the robot requires substantial intelligence or autonomy to fulfill its function. Between the two extrema lie a variety of *shared control* architectures, where some degree of autonomy or automated help is available to assist the user.

In practice, many systems involve at least some level of direct control and accept the user's motion commands via a joystick or similar device in the user interface. The joystick is an instrumented mechanism and can itself be viewed as a robot. The local and remote robots are called *master* and *slave* respectively, while the system is referred to as a *master–slave system*. To provide direct control, the slave robot is programmed to follow the motions of the master robot, which is positioned by the user. It is not uncommon for the master robot (joystick) to be a kinematic replica of the slave, providing an intuitive interface.

Some master–slave systems provide force feedback, such that the master robot not only measures motions but also displays forces to the user. The user interface becomes fully bidirectional and such telerobotic systems are often called *bilateral*. The human–master interactions are a form of human–robot interaction (Chap. 69). The field of haptics (Chap. 41) also discusses bidirectional user interfaces, involving both motion and force, though more commonly to interface the user with virtual instead of remote environments. We should note that both motion and force may become the input or output to/from the user, depending on the system architecture.

Finally, *telepresence* is often discussed as an ultimate goal of master–slave systems and telerobotics in general. It promises to the user not only the abil-

ity to manipulate the remote environment, but also to perceive the environment as if encountered directly. The human operator is provided with enough feedback and sensations to feel present in the remote site. This combines the haptic modality with other modalities serving the human senses of vision, hearing or even smell and taste. See videos [VIDEO 297](#), [VIDEO 318](#) and [VIDEO 319](#), and [VIDEO 321](#) for some early and recent results aiming for this telepresence. We focus our descriptions on the haptic channel, which is created by the robotic hardware and its control systems. The master–slave system becomes the medium through which the user interacts with the remote en-

vironment and ideally they are fooled into forgetting about the medium itself. If this is achieved, we say that the master–slave system is transparent.

While bilateral master–slave systems have held the biggest promise for telepresence and intuitive operations, they have also posed some of the largest stability and control problems. Especially considering force feedback from sensors at the remote site, these systems close multiple interwoven feedback loops and have to deal with large uncertainties in the environment. They have received heavy research attention and will therefore be a repeated focus in some of our following discussions.

43.2 Telerobotic Systems and Applications

Telerobotic systems, like most robotic devices, are typically designed for specific tasks and according to explicit requirements. As such, many unique systems have evolved, of which we present an overview for different applications. We begin with a short historical perspective, then describe different applications with various robot designs and user interfaces.

43.2.1 Historical Perspective

Teleoperation enjoys a rich history and dates back to nuclear research by Raymond C. Goertz in the 1940s and 1950s. In particular, he created systems for humans to handle radioactive material from behind shielded walls. The first systems were electrical, controlled by an array of on–off switches to activate various motors and move various axes [43.3]. Without any feel, these manipulators were *slow and somewhat awkward to operate*, leading *Goertz* to build pairs of mechanically linked master–slave robots [43.3, 4]. Connected by gears, linkages, and cables, these systems allowed the operator to use natural hand motions and transmitted forces and vibrations through the connecting structure (Fig. 43.2). Unfortunately they limited the distance between the operator and environment and required the use of kinematically identical devices. *Goertz* quickly recognized the value of electrically coupled manipulators and laid the foundations of modern telerobotics and bilateral force-reflecting positional servos [43.5].

At the beginning of the 1960s the effects of time delay on teleoperation started to become a topic of research [43.6, 7]. To cope with this problem the concept of supervisory control was introduced [43.2] and inspired the next years of development. In the late 1980s and early 1990s theoretical control came into play with Lyapunov-based analysis and network theory [43.8–

13]. Using these new methods, bilateral control of telerobotic systems became the vital research area it is today (Sect. 43.4). The growth of the Internet and its use as a communication medium has further fueled this trend, adding the challenges of nondeterministic time delay.

On the hardware side, the Central Research Laboratory model M2 of 1982 was the first telerobotic system which realized force feedback while separating master and slave electronics. It was developed together with the Oak Ridge National Laboratory and was used for some time for a wide range of demonstration tasks including military, space or nuclear applications. The National Aeronautics and Space Administration (NASA) tested the M2 system to simulate the ACCESS space truss assembly with excellent results (Fig. 43.3). The ad-

vanced servomanipulator (**ASM**) was developed from the M2 to improve the remote maintainability of manipulators and intended as a foundation for telerobotic systems [43.14].

Also driven by the nuclear application, bilateral servomanipulators for teleoperation were developed in France at the Commission de Energie Atomique (**CEA**) by *Vertut* and *Coiffet* [43.15]. With the MA 23 they demonstrated telerobotic operation including computer-assisted functionalities to improve the operator's performance [43.16]. The assistance included software jigs and fixtures or virtual walls and restrictions [43.17] (Sect. 43.3.2).

For space applications a dual-arm force reflecting telerobotic system was developed by *Bejczy* at the Jet Propulsion Laboratory (**JPL**) [43.18] and  **VIDEO 298**. This system was the first use of kinematically and dynamically different master and slave robots. It required control in the Cartesian space coordinates of the operator's hand and slave robot's tool. Figure 43.4 shows the master control station with its two back-drivable hand controllers. The system was used to simulate teleoperation in space.

In 1993 the first telerobotic system was flown in space with the German Spacelab Mission D2 on board

the Space Shuttle Columbia. The robot technology experiment (ROTEX), shown in Fig. 43.5, demonstrated remote control of a space robot by means of local sensory feedback, predictive displays, and teleoperation [43.19]. In this experiment the round trip delay was 6–7 s, such that it was not feasible to include force feedback into the control loop.

Throughout the 1980s and 1990s, as nuclear power activities began to decline, interests expanded into new areas including medicine and undersea operations. Ef-

Fig. 43.6 Operation Lindberg. The first transcontinental telerobotic surgery (2001) (courtesy M. Ghodoussi)

forts were accelerated by the availability of increasing computer power as well as the introduction of novel hand controllers, e.g., the PHANTOM device [43.20], popularized by haptic applications in virtual reality (Chap. 41).

Simultaneously, surgery was seeing the trend toward minimally invasive techniques, highlighted by the first laparoscopic cholecystectomy (removal of the gallbladder) in 1987. Several groups saw the potential for telerobotics and pursued telesurgical systems. Most noteworthy are the Telepresence Surgery System developed at the Stanford Research Institute (now SRI International) in 1987 [43.21], the Laparoscopic Assistant Robotic System (LARS) created at the IBM Watson Research Center [43.22], the teleoperated surgical instrument Falcon designed at MIT (Massachusetts Institute of Technology) [43.23], and the Robot As-

sisted Microsurgery (RAMS) workstation developed at JPL [43.24].

In 1995 Intuitive Surgical Inc. was founded to leverage several of these concepts, leading to the da Vinci telesurgical system [43.25] and its introduction to market in 1999. Meanwhile Computer Motion started with a voice-controlled robot moving an endoscopic camera [43.26] and extended those capabilities into the

ZEUS system. In 2001 a surgeon in New York (USA) used a ZEUS system to perform the first transatlantic telesurgical laparoscopic cholecystectomy on a patient located in Strasbourg (France) [43.27], as depicted in Fig. 43.6. The system did not include force feedback, so the surgeon had to rely on visual feedback only.

In this perspective we have given reference only to the systems that may be seen as milestones within the history of telerobotics. Other systems, which have been developed and added value to the research field, unfortunately could not be mentioned here.

43.2.2 Applications

Telerobotic systems have been motivated by issues of human safety in hazardous environments (e.g., nuclear or chemical plants), the high cost of reaching remote environments (e.g., space), scale (e.g., power amplification or position scaling in micromanipulation or minimally invasive surgery), and many others. Not surprisingly, after their beginning in nuclear research, telerobotic systems have evolved to many fields of application. Nearly everywhere a robot is used, telerobotic systems can be found. The following are some of the more exciting uses.

In minimally invasive surgery telerobots allow procedures to be performed through small incisions, reducing the trauma to the patient compared to traditional surgery [43.28]. The da Vinci system, made by Intuitive Surgical Inc. [43.25] and shown in Fig. 43.7, is the only commercially available device at present. Other ef-

forts, however, have included computer motion [43.26] and endoVia Medical [43.29] on the commercial side, as well as the University of Washington [43.30], Johns Hopkins University [43.31], the German Aerospace Center [43.32], and many others (see VIDEO 322).

Protecting the operator from having to reach into a hazardous environment, telerobotic systems are widely used in nuclear or chemical industry. Some systems have been developed for the maintenance of high-voltage electrical power lines, which can be safely repaired without service interruption by a human operator using a telerobotic system. Disarming of explosives is another important task. Many systems like the telerob explosive ordnance disposal and observation robot (tEODor) shown in Fig. 43.8 or PackBot, made by iRobot [43.33], are used by police and military to disarm mines and other explosives. Similar vehicles are remote controlled for search and rescue in disaster zones [43.34].

Space robotics is a classic application, in which distance is the dominating barrier, as discussed in Chap. 55. The NASA rovers on Mars are a famous example. Due to the time delay of several minutes, the rovers are commanded using supervisory control, in which the human operator is defining the goal of a movement and the rover achieves the goal by local autonomy using sensory feedback directly [43.35].

In orbital robotics the German technology experiment ROKVISS (robot component verification on the international space station (ISS)) was the most advanced telerobotic system [43.36]. Launched in 2004 and operational through 2010, it was installed outside the Russian module of the international space station. It validated advanced robot components in the slave system, including torque sensors and stereo video cameras, in real space conditions. Using a direct communication link between the space station and the operator station at DLR (German Aerospace Center), the time delay was kept at about 20 ms allowing a bilateral control architecture with high-fidelity force feedback to the operator [43.37] (Fig. 43.9). This technology is leading toward robotic service satellites, called Robonauts, which can be controlled remotely from the ground to help real astronauts during extravehicular activities (EVA) or to perform repair and maintenance tasks [43.38].

43.3 Control Architectures

Compared to plain robotic systems, in which a robot executes a motion or other program without further consultation of a user or operator, telerobotic systems provide information to and require commands from the user. Their control architectures can be described by the style and level of this connection, as shown in

Fig. 43.10. Organized in a spectrum, the three main categories are:

- Direct control
- Shared control
- Supervisory control.

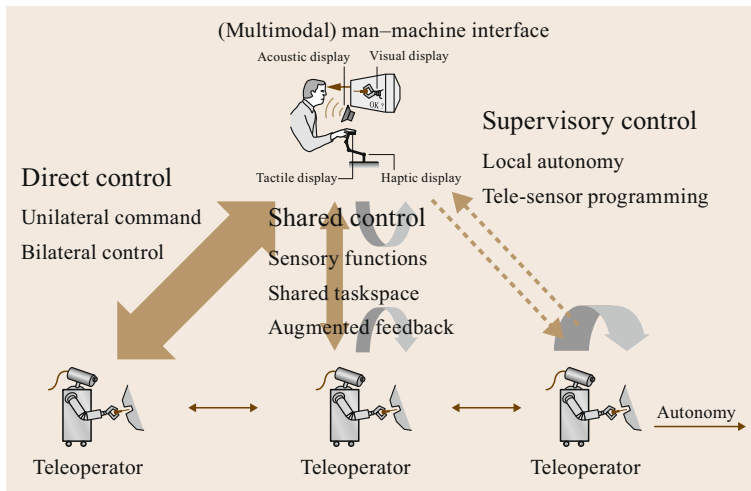

Fig. 43.10 Different concepts for telerobotic control architectures

In practice, however, control architectures often include parts of all strategies.

Direct control implies no intelligence or autonomy in the system, so that all slave motion is directly controlled by the user via the master interface. This may incorporate sensory feedback to the user in a bilateral configuration. If the slave motion is controlled by a combination of direct user commands and local sensory feedback or autonomy, the architecture is denoted as shared control. It is similarly shared if user feedback is augmented from virtual reality or by other automatic aids. In supervisory control user commands and feedback occur at a higher level. The connection is more loose and the slave has to rely on stronger local autonomy to refine and execute tasks. The following explains the architectures in reverse order, leading to a detailed treatment of direct and bilateral control in Sect. 43.3.3, which introduces the basic ideas for Sect. 43.4.

43.3.1 Supervisory Control

Supervisory control, introduced by *Ferrell* and *Sheridan* in 1967 [43.2], is derived from the analog of supervising a human subordinate staff member. The supervisor gives high-level directives to and receives summary information from, in this case, the robot. *Sheridan* describes this approach in comparison with manual and automatic robot control [43.39]:

Human operators are intermittently programming and continually receiving information from a computer that itself closes an autonomous control loop through artificial effectors and sensors.

In general, supervisory control techniques will allow more and more autonomy and intelligence to shift to the robot system. Today simple autonomous control

loops may be closed at the remote site, with only state and model information being transmitted to the operator site. The operator supervises the telerobotic system closely and decides exactly how to act and what to do. A specific implementation of supervisory control is the telesensor programming approach, which is presented hereafter. See also [VIDEO 299](#) for another implementation of supervisory control for space operation.

Telesensor Programming

Developed for space applications with large communication delays, the telesensor programming (TSP) approach has been characterized as a *task-level-oriented programming technique* and *sensor-based teaching by showing* [43.40, 41]. In essence, operators interact with a complex simulation of the robot and remote environment, in which they can test and adjust tasks. The tasks, consisting of robot and environment signals and configuration parameters, are then uploaded to the remote site. The approach presumes that the sensor systems provide sufficient information about the actual environment so that the tasks can be executed autonomously. Specifications and high-level planning remain the responsibility of the human operator.

Figure 43.11 shows the structure of a TSP implementation, consisting of two control loops working in parallel. One loop controls the real (remote) system, which contains internal feedback for local autonomy. The other loop establishes a simulation environment which is structurally equivalent to the real system, with a few exceptions. Most importantly, any signal delay which may result from communication to the remote system, in particular in space applications, is not duplicated in the simulation. This makes the simulation predictive with respect to the real system. A second exception is the display of internal variables in the sim-

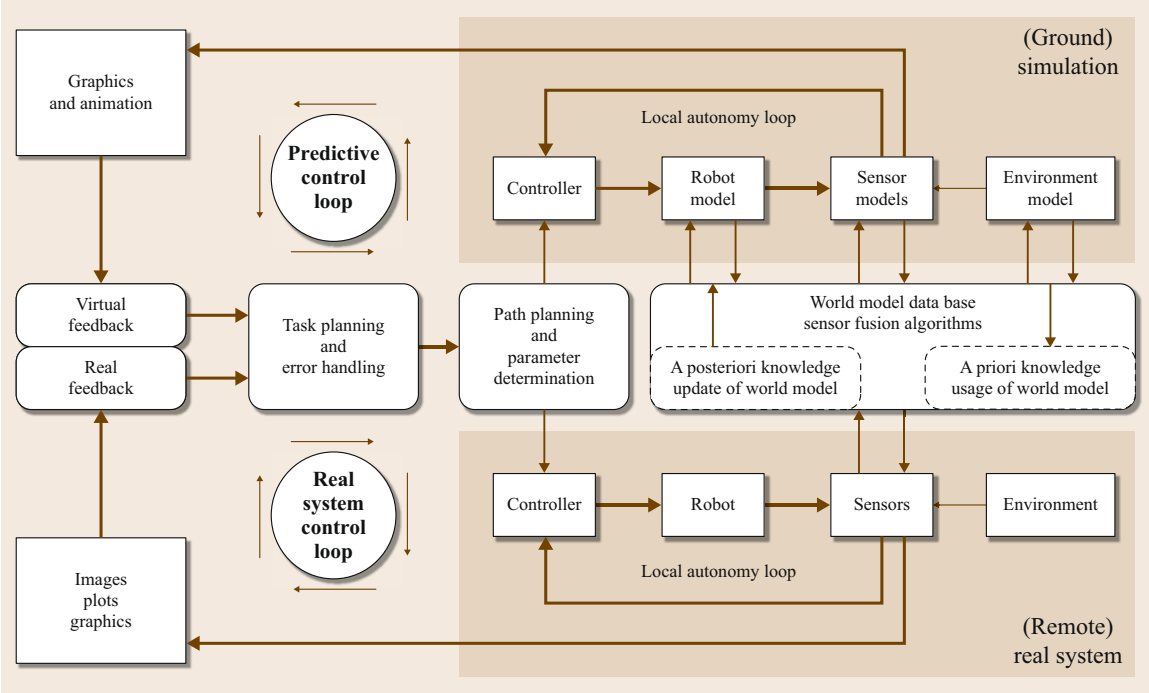

Fig. 43.11 The concept of telesensor programming as demonstrated during the ROTEX mission

ulation, which cannot be observed (measured) in the real system. This gives the operator or task planner more insight into what is happening or may happen in the system in response to commands. Communication between the two loops occurs via a common model data base which delivers a priori knowledge for execution on the remote system and a posteriori knowledge for model updating in the simulated world.

Unique tools are necessary to implement the functionality required for such a telerobotic control system. First a sophisticated simulation system has to be pro-

vided to emulate the real robot system. This includes the simulation of sensory perception within the real environment. Also, the operator needs an efficient interface to set up task descriptions, to configure the task control parameters, to decide what kind of sensors and control algorithms should be used, and to debug an entire job execution phase.

For telerobotic systems with large time delays of a few seconds or more, e.g., in space and undersea applications, such a sensor-based task-directed programming approach has advantages. It is not feasible for human operators to handle the robot movements directly under delayed visual feedback. Only a predictive simulation allows the operator to telemanipulate the remote system [43.42]. In addition, the use of force reflecting hand controllers to feed back force signals from the simulated predicted world can improve the operator's performance [43.43]. Finally, an interactive supervisory user interface makes it possible to configure the environmental and control parameters.

43.3.2 Shared Control

Shared control tries to combine the basic reliability and sense of presence achievable by direct control with the smarts and possible safety guarantees of autonomous control ([43.44, 45] and VIDEO 299). This may occur in various forms. For example, the slave robot may need

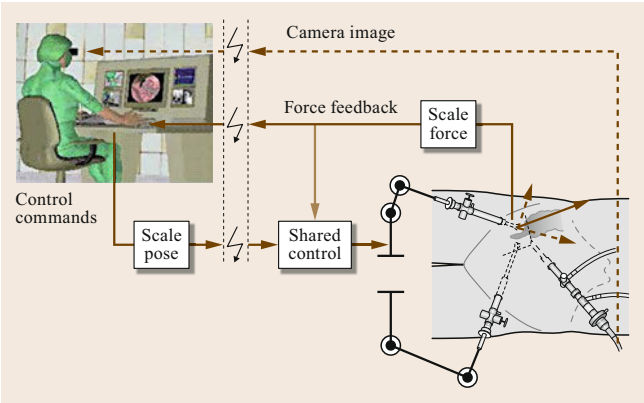

Fig. 43.12 An example for the shared control concept in telerobotic surgery

to correct motion commands, regulate subsets of joints or subtasks, or overlay additional commands.

With large communication delays, a human operator may only be able to specify gross path commands, which the slave must fine-tune with local sensory information [43.46]. We may also want the slave to assume control of subtasks, such as maintaining a grasp over long periods of time [43.47]. And in surgical applications, shared control has been proposed to compensate for beating heart movements (Fig. 43.12). The sensed heart motion is overlaid on the user commands, so the surgeon can operate on a virtually stabilized patient [43.48].

A special application of shared control is the use of *virtual fixtures* ([43.49–51] and  VIDEO 72). Virtual elements, such as virtual surfaces, virtual velocity field, guide tubes, or other appropriate objects, are superimposed into the visual and/or haptic scene for the user. These fixtures can help the operator perform tasks by limiting movement into restricted regions and/or influencing movement along desired paths. Control is thus shared at the master site, taking advantage of pre-knowledge of the system or task to modify the user's commands and/or to combine them with autonomously generated signals.

Capitalizing on the accuracy of robotic systems while sharing control with the operator, telerobotic systems with virtual fixtures can achieve safer, faster and more intuitive operation. *Abbott et al.* describe the benefits by comparison to the common physical fixture of a ruler [43.50]:

A straight line drawn by a human with the help of a ruler is drawn faster and straighter than a line drawn freehand. Similarly, a [master] robot can apply forces or positions to a human operator to help him or her draw a straight line.

Based on the nature of the master robot and its controller, the virtual fixtures may apply corrective forces or constrain positions. In both cases, and in contrast to physical fixtures, the level and type of assistance can be programmed and varied.

43.3.3 Direct and Bilateral Teleoperation

To avoid difficulties in creating local autonomy, most telerobotic systems include some form of direct control: they allow the operator to specify the robot's motions. This may involve commanding either position or velocity or acceleration. We begin our discussions with the later two options, which are generally implemented unilaterally without force feedback to the user. We then focus on position control, which is more suited to bilateral operation. We will assume a master–slave system,

i. e., the user is holding a joystick or master mechanism serving as an input device.

Unilateral Acceleration or Rate Control

For underwater, airborne, or space applications, a slave robot may be a vehicle actuated by thrusters. Direct control thus requires the user to power the thrusters, which in turn accelerates the vehicle. For other applications, the user may be required to command the rate or velocity of the vehicle or slave robot. In both scenarios, the input device is commonly a joystick, often spring centered, where the acceleration or rate commands are proportional to the joystick displacement. For six degree-of-freedom (DOF) applications, i. e., when the slave needs to be controlled in translation and orientation, a six-dimensional (6-D) space mouse can be used. Alternatively two joysticks may separately command translation and orientation.

Acceleration and rate control are very attractive when the master and slave robots are fundamentally different, for example if the slave robot can reach an effectively unbounded workspace. Unfortunately, basic implementations can require considerable effort for the operator to reach and hold a given target location. As expected, users can more accurately position a system under rate control than under acceleration control [43.52]. Indeed acceleration control necessitates users to regulate a second-order system versus a first-order system for rate control. Assuming the slave has local position feedback available, a control system is often incorporated locally, such that the user may specify position commands and is relieved from the dynamic control problem. We refer to Sect. 43.5.1 for some emerging developments for bilateral control of mobile robots.

Position Control and Kinematic Coupling

Assuming that the slave is under position control, we can consider a kinematic coupling between master and slave, i. e., a mapping between master and slave positions. In particular, we must remember that the master mechanism moves in the master workspace, while the slave robot moves in the slave workspace. The mapping connects these two spaces, which are nearly always somewhat different.

Clutching and Offsets. Before discussing how the two robots are coupled, we must understand that they are not always coupled. For example, before the system is turned on, master and slave robots may, for whatever reason, be placed in some initial position/configuration. We have three options of how to engage the system:

1. First autonomously move one or both robots so they come to the same position

2. Wait until someone (the user) externally moves one robot to match the location of the other, or
3. Connect the two robots with some offset.

Once connected, most systems also allow a temporary disconnection between the two sites. The reason is twofold: to allow the user to rest without affecting the slave state and to allow a shift between the two robots. The later is most important if the workspaces of both robots do not perfectly overlap. This is much like picking up your mouse off your mouse pad to reposition without moving the cursor. In telerobotics the process is called *clutching* or sometimes *indexing*. If clutching is allowed, or both robots are not constrained to start at the same location, the system must allow for offsets between the two robots.

When clutched or disconnected, most systems hold the slave at rest or allow it to float in response to environment forces. It is also possible for the slave to retain its preclutching momentum and continue moving, similar to kinetic scrolling popularized in smartphones [43.53].

Kinematically Similar Mechanisms. The simplest scenario involves a master and slave mechanism that are kinematically equivalent if not entirely identical. In this case, the two robots can be connected at a joint level. With \mathbf{q} denoting joint values and subscripts “m” referring to the master, “s” to the slave, “offset” to a shared offset, and “d” to a desired value, we can write

$$\begin{aligned}\mathbf{q}_{sd} &= \mathbf{q}_m + \mathbf{q}_{\text{offset}} , \\ \mathbf{q}_{md} &= \mathbf{q}_s - \mathbf{q}_{\text{offset}} .\end{aligned}\quad (43.1)$$

At the instance the two robots are to be connected or reconnected, the offset is computed as

$$\mathbf{q}_{\text{offset}} = \mathbf{q}_s - \mathbf{q}_m .\quad (43.2)$$

Most kinematically similar master–slave systems have the same workspace at both sites and do not allow clutching. By construction the offset is then always zero.

Depending on the controller architecture, the joint velocities may be similarly related, taking derivatives of (43.1). An offset in velocities is not necessary.

Kinematically Dissimilar Mechanisms. In many cases, the master and slave robots differ. Consider that the master is connected to the human user and thus should be designed accordingly. Meanwhile the slave works in some environment and may have a very different joint configuration and different number of joints. As a result, connecting the robots joint by joint may not be feasible or appropriate.

Instead kinematically dissimilar robots are commonly connected at their tips. If \mathbf{x} is a robot’s tip position, we have

$$\begin{aligned}\mathbf{x}_{sd} &= \mathbf{x}_m + \mathbf{x}_{\text{offset}} , \\ \mathbf{x}_{md} &= \mathbf{x}_s - \mathbf{x}_{\text{offset}} .\end{aligned}\quad (43.3)$$

If orientations are also connected, with \mathbf{R} describing a rotation matrix, we have

$$\begin{aligned}\mathbf{R}_{sd} &= \mathbf{R}_m \mathbf{R}_{\text{offset}} , \\ \mathbf{R}_{md} &= \mathbf{R}_s \mathbf{R}_{\text{offset}}^T ,\end{aligned}\quad (43.4)$$

where the orientational offset is defined as slave relative to master

$$\mathbf{R}_{\text{offset}} = \mathbf{R}_m^T \mathbf{R}_s .\quad (43.5)$$

Again velocities and angular velocities may be connected if needed and do not require offsets.

Finally note that most telerobotic systems use a video camera at the remote site and a monitor at the local site. To make the connection appear natural, the slave position and orientation should be measured relative to the camera, while the master position and orientation should be measured relative to the user’s view.

Scaling and Workspace Mapping. Kinematically dissimilar master–slave robots are commonly also of different size. This means not only do they require clutching to fully map one workspace to another, but they often necessitate motion scaling. And so (43.3) becomes

$$\begin{aligned}\mathbf{x}_{sd} &= \mu \mathbf{x}_m + \mathbf{x}_{\text{offset}} , \\ \mathbf{x}_{md} &= \frac{(\mathbf{x}_s - \mathbf{x}_{\text{offset}})}{\mu} .\end{aligned}\quad (43.6)$$

The orientation, however, typically should not be scaled. The scale μ may be set to either map the two workspaces as best possible, or to provide the most comfort to the user.

If force feedback is provided, as described below, an equivalent force scale may be desired. This will prevent distortion of the remote environmental conditions, such as stiffness or damping, by the scaling. In addition to the motion and force scalings, it is also possible to directly achieve power scaling between master and slave systems [43.51].

Beyond linear scaling, several research efforts have created nonlinear or time-varying mappings, which deform the workspaces. These may effectively change the scale in the proximity of objects [43.54] or drift the offset to best utilize the master workspace [43.55].

Local Position and Advanced Control. By construction we are now assuming that the slave follows a position command. This necessitates a local slave controller to regulate its position. In particular for kinematically dissimilar mechanisms, this will be a Cartesian tip position controller (Chap. 7).

If the slave robot has redundancies or possesses a large number of DOFs, these may be controlled either

automatically to optimize some criterion or manually with additional user commands. Indeed some emerging applications are coordinating multiple users to control such complex systems. This is particularly relevant when the kinematic dissimilarity becomes extreme and has received considerable research attention. We refer here to Chap. 11 and especially Sect. 43.5 for appropriate techniques and new developments.

43.4 Bilateral Control and Force Feedback

In pursuit of telepresence and to increase task performance, many master–slave systems incorporate force feedback. That is, the slave robot doubles as a sensor and the master functions as a display device, so that the system provides both forward and feedback pathways from the user to the environment and back. Figure 43.13 depicts the common architecture viewed as a chain of elements from the user to the environment.

The bilateral nature of this setup makes the control architecture particularly challenging: multiple feedback loops form and even without environment contact or user intervention, the two robots form an internal closed loop. The communications between the two sites often inserts delays into the system and this loop, so that stability of the system can be a challenging issue [43.56].

To present force information without stability problems, it is possible to use alternate displays, such as audio or tactile devices [43.57]. Meanwhile, the combination of vibrotactile methods with explicit force feedback can increase high-frequency sensations and provide benefits to the user [43.58]. Tactile shape sensing and display also extends the force information presented to the user [43.59].

In the following we discuss explicit force feedback. We first examine the basic architectures before discussing stability and some advanced techniques.

43.4.1 Position/Force Control

Two basic architectures couple the master and slave robots: position–position and position–force. We assume that the robot tips are to be connected by the equations of Sect. 43.3.3 and give the control laws for

translation. Control of orientation or joint motions follows equivalent patterns.

Position–Position Architecture

In the simplest case, both robots are instructed to track each other. Both sites implement a tracking controller, often a proportional–derivative (PD) controller, to fulfill these commands,

$$\begin{aligned} F_m &= -K_m(\mathbf{x}_m - \mathbf{x}_{md}) - B_m(\dot{\mathbf{x}}_m - \dot{\mathbf{x}}_{md}), \\ F_s &= -K_s(\mathbf{x}_s - \mathbf{x}_{sd}) - B_s(\dot{\mathbf{x}}_s - \dot{\mathbf{x}}_{sd}). \end{aligned} \quad (43.7)$$

If the position and velocity gains are the same ($K_m = K_s = K$, $B_m = B_s = B$), then the two forces are the same and the system effectively provides force feedback. This may also be interpreted as a spring and damper between the tips of each robot, as illustrated in Fig. 43.14. If the two robots are substantially different and require different position and velocity gains, some suitable force, position or power scalings, as explained in Sect. 43.3.3, may be utilized.

Note we have assumed the slave is under impedance control and back-drivable. If the slave is admittance controlled, i. e., it accepts position commands directly, the second part of (43.7) is unnecessary.

Also note that by construction the user feels the slave’s controller forces, which include forces associated with the spring–damper and slave inertia in addition to environment forces. Indeed while moving without contact, the user will feel the inertial and other dynamic forces needed to move the slave. Furthermore, if the slave is not back-drivable, i. e., does not easily move under environment forces, the environment force

Fig. 43.13 A typical bilateral tele-operator can be viewed as a chain of elements reaching from user to environment (CPU – central processing unit)

Fig. 43.14 A position–position architecture effectively creates a spring and damper between the two robots

may be entirely hidden from the user. Naturally this defeats the purpose of force feedback. In these cases, a local force control system may be used to render the slave back-drivable. Alternatively, a position–force architecture may be selected.

Position–Force Architecture

In the above position–position architecture, the user was effectively presented with the slave’s controller force. While this is very stable, it also means the user feels the friction and inertia in the slave robot, which the controller is actively driving to overcome. In many scenarios this is undesirable. To avoid the issue, position–force architectures place a force sensor at the tip of the slave robot and feedback the force from there. That is, the system is controlled by

$$\begin{aligned} F_m &= F_{\text{sensor}} , \\ F_s &= -K_s(x_s - x_{sd}) - B_s(\dot{x}_s - \dot{x}_{sd}) . \end{aligned} \quad (43.8)$$

This allows the user to only feel the external forces acting between the slave and the environment and presents a more clear sense of the environment. However, this architecture is less stable: the control loop passes from master motion to slave motion to environment forces back to master forces. There may be some lag in the slave’s motion tracking not to mention any delay in communications. Meanwhile the loop gain can be very high: a small motion command can turn into a large force if the slave is pressing against a stiff environment. In combination, stability may be compromised in stiff contact and many systems exhibit contact instability in these cases.

43.4.2 Passivity and Stability

The two basic architectures presented in Sect. 43.4.1 clearly illustrate one of the basic tradeoffs and chal-

lenges in force feedback: stability versus performance. Stability issues arise because any models of the system depend on the environment as well as the user. Both these elements are difficult to capture and, if we assume we want to explore unknown environments, impossible to predict. This issue makes a stability analysis very difficult. A common tool that avoids some of these issues is the concept of passivity. Although passivity provides only a sufficient (not a necessary) condition for stability, it incorporates the environmental uncertainty very well.

Passivity is an intuitive tool that examines the energy flows in a system and makes stability assertions if energy is dissipated instead of generated. Three rules are of importance here. First, a system is passive if and only if it cannot produce energy. That is the output energy from the system is limited by the initial and accumulated energy in the system. Second, two passive systems can be combined to form a new passive system. Third, the feedback connection of two passive systems is stable.

In the case of telerobotics, we generally assume that the slave robot will only interact with passive environments, that is, that the environments do not contain active motors or the like. Without the human operator, stability can therefore be assured if the system is also passive, without needing an explicit environment model.

On the master side the operator closes a loop and has to be considered in the stability analysis. In general, the master robot will be held by the user’s hand and arm. A variety of models and parameters describe the human arm dynamics, mainly in the form of a mass–damper–spring system. In [43.60] we find a summary of model parameters used by different authors. For an impedance-controlled haptic interface, found in many systems, the operator adds some physical damping and a light touch ($F_{\text{human}} \approx 0$) is often one of the more challenging scenarios [43.61, 62]. As such some analyses ignore the human operator entirely. But even in general, humans seem to achieve stable interactions with all passive systems and passivity is usually considered sufficient for stable human–telerobot interactions.

To apply passivity, we take the system originally depicted in Fig. 43.13 and describe it as two-port elements in Fig. 43.15. Each port describes the energy flow between subsystems, where power is the product of a pair

Fig. 43.15 A teleoperator can be analyzed as a chain of two port elements connecting the one-port operator to the one-port environment

of collocated physical variables. We can choose a sign convention, for example declaring positive power to flow toward the remote environment. Then at the first boundary, the positive power flow is the product of master velocity $\dot{\mathbf{x}}_m$ times applied (human) force $\mathbf{F}_{\text{human}}$

$$P_{\text{left}} = \dot{\mathbf{x}}_m^T \mathbf{F}_{\text{human}}. \quad (43.9)$$

Meanwhile at the last boundary, the positive power flow is the product of the slave velocity $\dot{\mathbf{x}}_s$ times the environment force \mathbf{F}_{env} (which ultimately opposes the human force)

$$P_{\text{right}} = \dot{\mathbf{x}}_s^T \mathbf{F}_{\text{env}}. \quad (43.10)$$

Therefore the entire telerobotic system is passive if

$$\begin{aligned} \int_0^t P_{\text{input}} dt &= \int_0^t (P_{\text{left}} - P_{\text{right}}) dt \\ &= \int_0^t (\dot{\mathbf{x}}_m^T \mathbf{F}_{\text{human}} - \dot{\mathbf{x}}_s^T \mathbf{F}_{\text{env}}) dt \\ &> -E_{\text{store}}(0). \end{aligned} \quad (43.11)$$

Obviously, the ideal teleoperator ($\dot{\mathbf{x}}_m = \dot{\mathbf{x}}_s$, $\mathbf{F}_{\text{human}} = \mathbf{F}_{\text{env}}$) is passive. These definitions can also be generalized to six dimensional twists and wrenches.

To simplify the analysis, we can examine the passivity of each two-port element or subsystem and then deduce the overall passivity. The master and slave robots are mechanical elements and hence passive. The controllers of a position–position architecture mimic a spring and damper, which are also passive elements. So without delay and ignoring discretization, a simple position–position architecture is passive. The following sections will address some of these limitations and thus create controllers that are passive under more circumstances.

While powerful to handle uncertainty, passivity can be overly conservative. Many controllers are overdamped if every subsystem is passive. In contrast, the combination of an active and a passive subsystem may be passive and stable and show less dissipation. This is particularly true for the cascaded arrangement of two-port elements in the telerobotic system of Fig. 43.15. From network theory, the Llewellyn criterion specifies when a possibly active two-port connected with any passive one-port becomes passive. This two-port is then labeled unconditionally stable, as it will be stable in connection to any two passive one-ports. The Llewellyn criterion may hence be used as a more

general stability test for telerobotic systems or components [43.63].

Passive controllers are also limited as they cannot hide the dynamics of the slave robot. In the above position–position architecture, the user will feel the forces associated with the slave inertia. In contrast the position–force architecture hides the slave inertia and friction from the user. As such, when the user inserts kinetic energy into the master without feeling any resistance, the system itself creates and injects the kinetic energy for the slave. This violates passivity and provides another insight as to why the architecture suffers from potential stability problems.

43.4.3 Transparency and Multichannel Feedback

Both basic architectures can be captured by the general teleoperator control system described by Lawrence [43.13], and later expanded by Hashtrudi-Zaad and Salcudean [43.63] and shown in Fig. 43.16. Ideally a system will equalize both the operator and environment forces as well as the master and slave motions. Therefore, it is desirable to measure both force and velocity (from which position may be integrated or vice versa) at both sites. With this complete information, the slave may, for example, start moving as soon

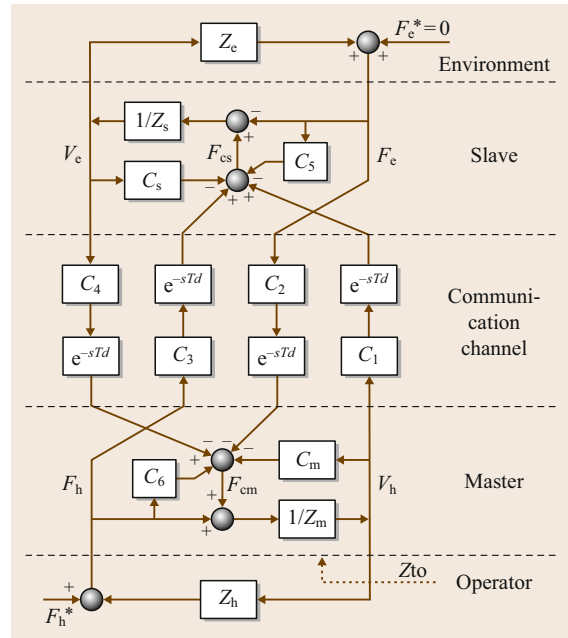

Fig. 43.16 In general, a controller will use both position and force information from both master and slave robot (after [43.63], adapted from [43.13])

as the user applies a force to the master, even before the master itself has moved.

Following these concepts derived in [43.13], we can examine the relationships between velocity and force, in the form of impedances and admittances. Note we do this in a single degree of freedom, assuming that all degrees of freedom may be treated independently. The environment will exhibit some impedance $Z_e(s)$ that is not known in advance and relates the environment force to the slave's velocity

$$F_e(s) = Z_e(s)v_s(s). \quad (43.12)$$

If we describe the teleoperator in whole as a two-port with a hybrid matrix formulation

$$\begin{pmatrix} F_h(s) \\ v_m(s) \end{pmatrix} = \begin{pmatrix} H_{11}(s) & H_{12}(s) \\ H_{21}(s) & H_{22}(s) \end{pmatrix} \begin{pmatrix} v_s(s) \\ -F_e(s) \end{pmatrix}, \quad (43.13)$$

then the user will perceive the impedance

$$Z_{to}(s) = \frac{F_h(s)}{v_m(s)} = (H_{11} - H_{12}Z_e)(H_{21} - H_{22}Z_e)^{-1}. \quad (43.14)$$

Transparency describes how close the user's perceived impedance comes to recreating the true environment impedance.

For a detailed treatment of passivity in telerobotics, impedance and admittance interpretations and designs, and transparency, we refer to some of the seminal works in [43.11–13, 63–66].

43.4.4 Time Delay and Scattering Theory

When delays occur in the communications between the local and remote site, even position–position architectures can suffer from serious instabilities [43.67, 68]. This can be traced to the communications block in Fig. 43.15, where the power entering the left side and exiting the right side do not add up. Rather energy may be generated inside the block, which feeds the instability [43.9].

Several approaches to operate under delay have been studied [43.69], in particular shared compliant control [43.70] and the addition of local force loops [43.71]. The use of the Internet for communication, adding variability to the delay, is also an area of interest [43.72, 73]. This further evokes issues of data reduction [43.74].

Here we note that natural wave phenomena are bilateral passive elements that tolerate delay. If the control system is described in the frequency domain and scattering matrices are used in place of impedance

and admittance matrices, the system can tolerate delays [43.75]. Scattering matrices relate the sum of velocity and force to their difference, so that passivity becomes a condition on the system gain, which is unaffected by the delay.

43.4.5 Wave Variables

Building on the realization that delay communications can be active and that wave phenomena circumvent the issue, wave variables provide an encoding scheme that is tolerant of delay [43.76]. Consider the power flowing through the system and separate the power moving forward and returning.

$$P = \dot{\mathbf{x}}^T \mathbf{F} = \frac{1}{2} \mathbf{u}^T \mathbf{u} - \frac{1}{2} \mathbf{v}^T \mathbf{v} = P_{\text{forward}} - P_{\text{return}}, \quad (43.15)$$

where the forward and returning power are by construction nonnegative. This leads to the definition of the wave variables

$$\mathbf{u} = \frac{b\dot{\mathbf{x}} + \mathbf{F}}{\sqrt{2b}}, \quad \mathbf{v} = \frac{b\dot{\mathbf{x}} - \mathbf{F}}{\sqrt{2b}}, \quad (43.16)$$

where \mathbf{u} is the forward-moving and \mathbf{v} the returning wave.

If velocity and force signals are encoded into wave variables, transmitted across the delay, and decoded at the far site, the system remains passive regardless of delay. In fact, in the wave domain, passivity corresponds to a wave gain of less than or equal to unity. No requirements are placed on phase and so lag does not destroy stability.

The wave impedance b relates velocity to force and provides a tuning knob to the operator. Large b values mean the system increases force feedback levels at the cost of feeling high inertial forces. Small values of b lower any unwanted sensations, making it easy to move quickly, but also lower the desirable environment forces. Ideally the operator would lower b when there is no risk of contact and raise b when contact is imminent. The concept of scattering has also been extended to a coordinate free context [43.77].

Recent developments are incorporating both position–position and position–force architectures within the wave frame work, so the resulting systems are stable with any environment, stable with any delay, yet maintain the feedback of high-frequency forces that help the operator identify happenings at the remote site [43.78]. To improve performance and assist the operator, especially across the Internet, predictors may also be incorporated [43.79].

43.4.6 Teleoperation with Lossy Communication

The Internet provides an affordable and ubiquitously accessible communication medium. However, it can also introduce nondeterministic effects and lossy connections due to time-varying delays, packet losses, and packet reordering. How to achieve passive bilateral teleoperation over such lossy communication network has been an active research topic in telerobotics.

Many telerobotic systems have relied on the position-position architecture (43.7) with extra damping injection. This leads to the following proportional-derivative (PD) control law, with a simple structure and explicit position feedback,

$$\begin{aligned} F_m &= -B_d \dot{x}_m(t) - B[\dot{x}_m(t) - \dot{x}_s(t - \tau_1)] \\ &\quad - K[x_m(t) - x_s(t - \tau_1)] \\ F_s &= -B_d \dot{x}_s(t) - B[\dot{x}_s(t) - \dot{x}_m(t - \tau_2)] \\ &\quad - K[x_s(t) - x_m(t - \tau_2)], \end{aligned} \quad (43.17)$$

where B_d , K , B are the stabilizing absolute damping and the PD control gains, and $\tau_1, \tau_2 \geq 0$ are the communication delays from slave to master and from master to slave, respectively.

The usage of this controller across lossy communication was yet hampered (or at least reserved) due to the lack of theoretical guarantees for its passivity and stability. Anecdotes say that with sufficiently large damping and small delays and PD gains, the closed-loop system remains stable. This anecdotal observation was justified in [43.80] for the case of constant delay, that is, the PD-like controller (43.17) is passive if the following condition is met,

$$B_d > \frac{\bar{\tau}_1 + \bar{\tau}_2}{2} K, \quad (43.18)$$

where $(\bar{\tau}_1 + \bar{\tau}_2)/2$ is the upper-bound of the round-trip delay, which can typically be estimated easily. Without human or environment forcing, master and slave positions will also converge to each other. This result was extended in [43.81] for the case of time-varying delay. Passivity of the PD-like controller (43.17) is guaranteed if

$$B_d > \frac{\sqrt{\bar{\tau}_1^2 + \bar{\tau}_2^2}}{2} K \quad \text{and} \quad |\dot{\tau}_i(t)| < 1, \quad (43.19)$$

where the second condition means the delay $\tau_i(t)$ neither grows nor decreases faster than time t . We refer to [43.81] for cases with asymmetric controller gains and to [43.82, 83] for extensions to general digital lossy communication networks.

With a fixed structure, the PD controller (43.17) has to be tuned to the worst-case conditions according to (43.18) and (43.19). It may thus exhibit drastic performance degradation for severely variable communications. To overcome such fixed structure limitation, several passivity-enforcing flexible control techniques have been recently proposed.

The technique of passivity-observer/passivity-controller (PO/PC) was originally devised for haptic device control [43.84] and has been extended for the bilateral teleoperation with digital network with time-varying delay [43.85–87]. Each PO does real-time bookkeeping of energy flows at the master and slave sites. The PC is activated to dissipate energy whenever a passivity violation is detected. The passive set-position modulation (PSPM) framework was proposed in [43.88], where the desired set-position signal received from a general digital lossy communication network is real-time modulated as close to the original set-position signal as possible, yet, only to the extent permissible by the available energy in the system. Passification of a desired control force utilizing the device's physical damping was addressed in [43.89] under the name of energy bounding algorithm (EBA). The idea of modulating a control signal or action under the passivity constraint was also adopted in the two-layer approach [43.90], where the transparency-layer is designed for best performance, while the passivity-layer superimposes constraints to enforce passivity.

Overall, the PO/PC approach may be considered as *corrective* (i.e., detect violation of passivity first and then apply passifying action) whereas the PSPM, EBA and the two-layer approaches are *preventive* (i.e., modulate/bound control action to prevent passivity violation). Interestingly, all the PO/PC, PSPM, EBA and two-layer approaches share some common characteristics: 1) they transmit energy packets along with other information over the communication network to replenish energy levels and enable useful work; and 2) each of these approaches activates their passifying action only when necessary, thus, can significantly improve control performance compared to fixed-structure teleoperation controllers, while also robustly enforcing passivity against a variety of communication imperfectness.

43.4.7 Port-Based Approaches

From Sect. 43.4.2 we know that energy flows provide a great description of telerobotic systems that physically interact with unknown environments and a human user. Indeed all physical interaction dynamics are fundamentally bound to energy exchanges. Passivity is a well suited analysis tool and assures stability if the system energy is bounded. All possible instabilities

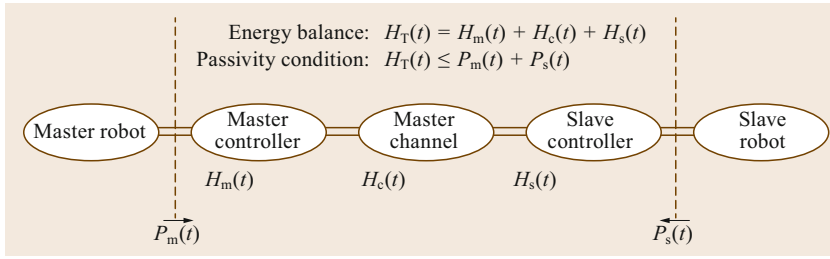

Fig. 43.17 Energy balance of the telemanipulation chain (after [43.90])

can be traced to unsupervised energy injections via the actuators. In Sect. 43.4.6 we also saw methods that explicitly monitor energy flows. Here we describe port-based approaches designed explicitly around energy exchanges. This can be advantageous to handle nonlinear system dynamics, discretization, time-varying delays, and other issues.

The concept of power ports and energy flows (Sect. 43.4.2) allows a precise analytical formulation of physical systems. This approach, which stems from concepts used in bond-graphs, enables a pure energy based analysis of complex nonlinear physical systems [43.91]. It has also provided new perspectives on modeling and robot control [43.92].

To handle sampling issues and prevent instabilities due to limited sampling rates, consider an energy-consistent discretization [43.93]. Rather than measuring power flow at discrete intervals, consider the energy flow that occurs continuously over the entire sampling interval. An exact measure of the energy transfer between sample time kT and the following sample time $(k+1)T$ is

$$\Delta E_k = \int_{kT}^{(k+1)T} \tau(t) \dot{q}(t) dt. \quad (43.20)$$

Assume an electric motor with an ideal current amplifier and without any commutation effects is generating the torque as commanded by a zero order hold (ZOH) digital to analog converter. Further assume the position sensor is collocated and synchronized to the ZOH transitions. The torque may then be considered constant during the interval, so that

$$\Delta E_k = \int_{kT}^{(k+1)T} \tau_{k,k+1} \dot{q}(t) dt. \quad (43.21)$$

Taking the torque out of the integral, we realize that

$$\Delta E_k = \tau_{k,k+1} [q(k+1) - q(k)]. \quad (43.22)$$

This simple result has far reaching consequences for interfacing the digital and physical world and can

be easily calculated even if the sampling time varies  **VIDEO 724**. And some of the assumptions may be relaxed with suitable adaptation. Using this more precise measurement of energy flow leads to more consistent energy book-keeping.

As it is shown in Fig. 43.17, we can now track energy in the digital world, associating individual available energy reservoirs H_m and H_s with the master and slave controllers. The communication channel transmits both data and energy packets (EPs), where EPs contain only information about an energy quanta. An EP is only sent if the transmitter has sufficient available energy, which is then decreased by the quanta. An arriving EP injects the quanta into the receiver's available energy. In this way the total *virtual* energy in the system will never increase. If the communication protocol allows an EP to be lost, this will remove energy similar to dissipation. This process is independent of any constant or variable delay.

The port-based paradigm allows any nonlinear control algorithm. But any applied control force will have an energetic consequence and will be allowed if and only if the associated available energy level is sufficiently high. Following the classification of Sect. 43.4.6, this paradigm is preventive. It prevents energy generation without needing to dissipate unexpected energy appearances.

Strategies are needed to address the exchange of energy between master and slave. A simple protocol introduced in [43.90] continually transmits EPs with a percentage of the locally stored energy. It can be shown that this will result in an equal distribution of energy between the master and slave controller. Also, if necessary, a small damper can be superimposed at the master side to extract energy from the human as needed.

With the port-based paradigm, the data communication (related to transparency) and the energy communication (related to passivity) are split: controllers may be nonlinear, energy and data transmission may be independent, and there is basically no restriction on the kind of controller which can be implemented. The fact that energy and data are separated gives the name to the two-layer approach [43.90].

43.5 Emerging Applications of Telerobotics

Historically, telerobotics research has focused on a conventional setup with two fixed-based robotic manipulators serving as the master and slave devices. Recently, there have been substantial efforts to extend the telerobotic theories and frameworks to more unconventional scenarios. Here we summarize some recent results on these emerging applications. The summary is by no means exhaustive and, to be consistent with the chapter, focuses on controls aspects and providing a stable bilateral user interface.

43.5.1 Telerobotics for Mobile Robots

Mobile robots are useful slave devices if the task covers a large spatial area. Flying robots, in particular, can operate in three-dimensional space without being bound to the ground. For mobile robot teleoperation, force feedback may be used to convey proprioceptive information of the slave robot (e.g., velocity), or haptic feedback of virtual (or real) objects in the remote environment.

A key difference of mobile and flying robot teleoperation compared to a conventional setup is *kinematic dissimilarity* [43.94]: the workspace of the master device is bounded while the workspace of the slave robot is unbounded. This suggests to couple the master position to the slave velocity, as with rate-control described in Sect. 43.3.3. A direct coupling between master position and slave velocity, however, cannot be addressed by the standard passivity framework (Sect. 43.4.2). The master position and the slave velocity possess different relative degrees with respect to the torque. One way to circumvent this difficulty is to utilize so called r -variable

$$r := \dot{q} + \lambda q. \quad (43.23)$$

That is, by utilizing inverse-dynamics similar to adaptive control design [43.95, 96] or by injecting some PD-type local state feedback with redefined output r [43.97] (Fig. 43.18), it is possible to render the master device to be passive with this r -variable replacing the velocity \dot{q} in its original passivity relation (43.9). This implies that we can couple the r -variable and the slave's velocity passively, just like standard passivity-based controllers.

Fig. 43.18 Feedback r -passivation by using PD-type state feedback

Meanwhile the r -variable contains the master position information.

We can also achieve passive mobile robot teleoperation with time-varying delays by extending the port-based ideas presented in Sect. 43.4.7 with the concept of a *virtual vehicle* [43.98]. This virtual vehicle is a simulated slave system, evolving in a gravitation-free field and having a finite energy tank. Commands from the master are only allowed to transfer energy from the tank to accelerate the vehicle or to return energy by decelerating the vehicle. This creates a closed energy system for the slave. A passive behavior can be achieved with a viscoelastic connection between the virtual and real vehicles.

Mobile telerobotics often uses nonholonomically-constrained wheeled mobile robots (WMRs) with pure-rolling wheels. For slave WMRs, it is often possible (with some low-level control as stated below) to split motions (i.e., velocity directions) into those requiring a position-velocity coupling as stated above (e.g., forward velocity of WMR), and others that may be controlled by a standard position-position coupling (e.g., rotation angle of WMR) as explained in Sects. 43.4.1 and 43.4.6.

Other mobile robots, particularly quadrotor or ducted-fan type aerial robots (Chap. 36) or thrust-propelled autonomous aquatic vehicles (AUVs, Chap. 25), are under-actuated with fewer control variables than degrees of freedom and also defy standard teleoperation techniques. To address under-actuation, *abstraction* of the slave robot has been utilized [43.98, 99], that is, human users telecontrol a fully-actuated *virtual system*, assuming that its motion is adequately describing that of the real slave robot, while a certain low-level tracking control is employed to drive the under-actuated slave mobile robot to tightly follow this virtual system. This abstraction leads to a hierarchical control design, composed of: 1) a high-level teleoperation control layer between the virtual vehicle and the master device; and 2) a low-level tracking control layer, into which the issue of the slave's under-actuation is confined.

For the teleoperation layer, we may then use the conventional teleoperation techniques explained in Sect. 43.4 with the (r, v) -coupling as explained above. We may also use the recently proposed control techniques explained in Sect. 43.4.6, which promise sharper haptic feedback with guaranteed stability against lossy communication. Presenting both the slave robot's proprioceptive information and the presence of surrounding objects for obstacle avoidance via the same haptic feedback channel, however, typically results in

a perceptual ambiguity [43.100]. A further perceptual modality (e.g., vision) is usually necessary to resolve this ambiguity. In some applications, the slave mobile robots are required to move around in but to not directly contact any physical environments. In these cases, virtual forces can be generated for any obstacles and the slave robot is interacting only with this precisely known virtual force field. This suggests it would be sufficient to enforce slave stability versus slave passivity ([43.99],  VIDEO 71 and  VIDEO 72), as a less conservative controller will likely give better system performance.

43.5.2 Multilateral Telerobotics

Many practical telerobotic tasks require dexterous, complicated, and large degree-of-freedom motions, e.g., in surgical training, rehabilitation, or exploration. For such tasks, we may utilize a team of multiple cooperative slave robots or a single slave robot possessing many degrees of freedom. The complexity involved in both cases may require multiple human operators to adequately control and coordinate all degrees of freedom. Following [43.102], we thus consider the following scenarios:

1. Single-master multiple-slave (SMMS) systems
2. Multiple-master multiple-slave (MMMS) systems
3. Multiple-master single-slave (MMSS) systems
4. Single-master single-slave (SMSS) systems, which constitute the conventional telerobotic setup.

Here we introduce some recent results applicable to SMMS and MMSS systems.

It is common for single-master multiple-slave (SMMS) systems to autonomously control simple sub-tasks among the slaves, e.g., maintaining a grasp, maintaining connectivity, or avoiding collisions (Fig. 43.19). In particular, in [43.101, 104, 105], passive decomposition [43.106] is utilized to decompose the dynamics of multiple slave robots into their shape system, describing the inter-slave formation aspects, and the locked system, abstracting their collective motion and centroid behavior. The locked system can be telecontrolled by a single human user, while an autonomous controller regulates the shape system to maintain the cooperative grasp of an object between the slaves.

Another interesting development in SMMS telerobotics is the combination with the frameworks of multi-agent cooperative control (i.e., consensus, flocking, synchronization, and other behaviors). For instance, in [43.103] and  VIDEO 73, a single human user directly telecontrols a single leader agent among the slaves, while the behavior of the other slaves is dictated by a leader-follower information graph (Fig. 43.20). A time-varying graph topology with arbitrary split/join operations among the slaves allows for reconfiguration, e.g., for navigation in cluttered environments. And the concept of virtual energy tanks, along with the port-Hamiltonian modeling and port-based approach (Sect. 43.4.7), is utilized to enforce passivity and stability of the total system.

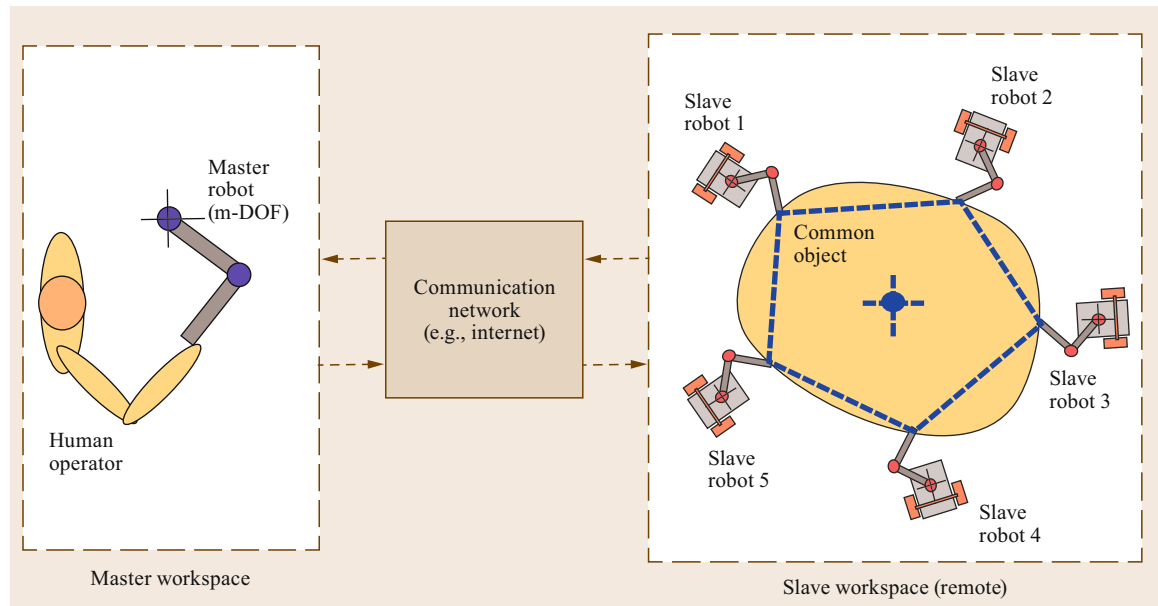

Fig. 43.19 SMMS telerobotic control of multiple slave robots (after [43.101])

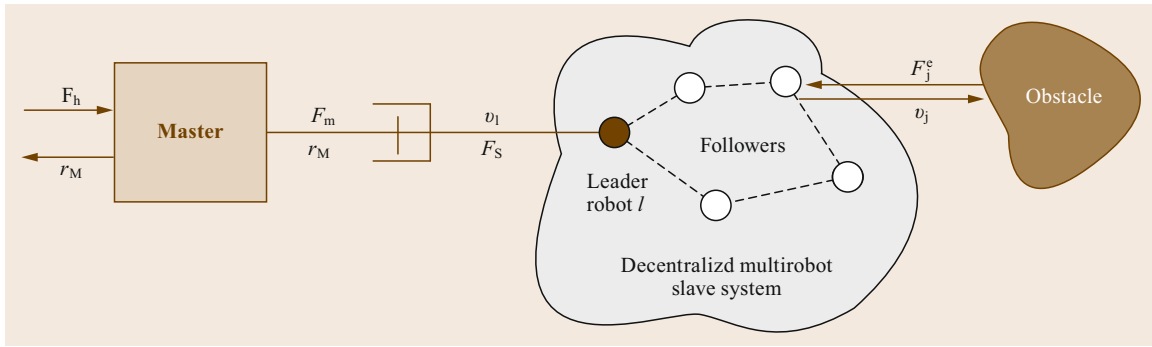

Fig. 43.20 SMMS telerobotic control architecture with possibly time-varying leader-follower information topology (after [43.103])

Fig. 43.21 SMMS control architecture for multiple unmanned aerial vehicles (UAVs; after [43.99]), where a single user telecontrols some of the virtual systems (via u_1^i, u_4^i) while telesensing the state of some of real UAVs (i.e., y_2, y_3), which are low-level controlled to follow their respective virtual systems

A distributed SMMS approach was also proposed in [43.99], in [VIDEO 71](#) and [VIDEO 72](#), to enable a single human user to telecontrol some of the slave robots. The inter-slave behaviors are encoded via a distributed artificial potential constructed on a time-invariant undirected information graph (Fig. 43.21). By using kinematic virtual systems to abstract the slave robots, the work achieves the combination of master-passivity and slave-stability. It guarantees no collisions among the slave robots or with obstacles and no separations among the slave robots.

A control approach for MMSS telerobotic systems was proposed in [43.107] and in [VIDEO 75](#), where two human users telecontrol distinct frames on a single large-DOF slave robot. The velocity space of the slave is decomposed according to the two command motions, resolving conflicts between and constraints imposed on them. Priority is given to the primary user's commands

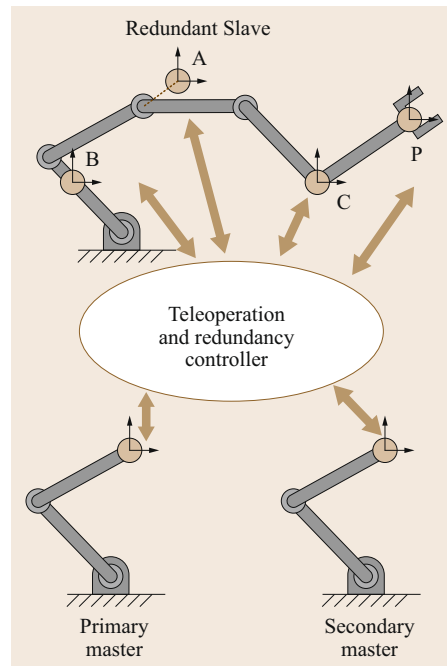

Fig. 43.22 Trilateral teleoperation (after [43.107]), where the primary master controls the end-effector frame P, while the secondary master controls task-space frame A, B or C: if A is chosen, primary and secondary tasks are non-conflicting/nonconstrained; if B is chosen, nonconflicting, yet, the secondary task is constrained; if C is chosen, conflicting, thus, prioritized nullspace control is necessary between primary and secondary tasks

(Fig. 43.22). The kinematics-level prioritized velocity commands are realized by dynamics-level adaptive control for all master and slave robots.

A different shared trilateral MMSS teleoperation framework was developed in [43.108], where two human users teleoperate the same point of a single slave

robot. Their control authority is adjusted with a dominance factor $\alpha \in [0, 1]$ set according to the task objective (e.g., $\alpha = 1$ for training or $\alpha = 0$ for evaluation). The MMSS system is optimized for a measure of transparency and Llewellyn's criteria is applied to the equivalent two-port system (with environment impedance Z_e embedded) to establish unconditional stability.

These multilateral and the previous mobile telerobotic approaches are promising to significantly expand the utility and application horizons of conventional telerobotics. Significant technical challenges and research questions remain, for example:

1. How to assign and determine the roles for multiple coordinating human users?
2. How to systematically split control tasks into teleoperative and autonomous control?
3. What are the most suitable performance measures, which are likely different from the conventional metrics?
4. What is the best form of human interface (or haptic feedback) [43.100] for the mobile and multilateral telerobotics and how to complement the interface with other modality (e.g., visual feedback).

43.6 Conclusions and Further Reading

Despite its age, telerobotics remains an exciting and vibrant area of robotics. In many ways, it forms a platform which can utilize the advances in robotic technologies while simultaneously leveraging the proven skills and capabilities of human users. Compare this, for example, with the development of the automobile and its relation to the driver. As cars are gradually becoming more sophisticated with added electronic stability control and navigation systems, they are becoming safer and more useful to their operators, not replacing them. Similarly telerobotics serves as a pathway for gradual progress and, as such, is perhaps best suited to fulfill robotics long-held promise of improving human life. It is seeing use in the challenging area of search and rescue. And with the recent developments and commercializations in telerobotic surgery systems, it is indeed impacting on the lives of tens of thousands of patients in a pro-

found fashion and extending the reach of robotics into our world.

For further reading in the area of supervisory control, we refer to *Sheridan* [43.39]. Though published in 1992, it remains the most complete discussion on the topic. Unfortunately few other books are devoted to or even fully discuss telerobotics. In [43.109] many recent advances, including methods, experiments, applications, and developments, are collected. Beyond this, in the areas of bilateral and shared control, as well as to understand the various applications, we can only refer to the citations provided. Finally, in addition to the standard robotics journals, we note in particular *Presence: Teleoperators and Virtual Environments*, published by the MIT Press. Combined with virtual-reality applications, it focuses on technologies with a human operator.

44. Networked Robots

Dezhen Song, Ken Goldberg, Nak-Young Chong

As of 2013, almost all robots have access to computer networks that offer extensive computing, memory, and other resources that can dramatically improve performance. The underlying enabling framework is the focus of this chapter: networked robots. Networked robots trace their origin to telerobots or remotely controlled robots. Telerobots are widely used to explore undersea terrains and outer space, to defuse bombs and to clean up hazardous waste. Until 1994, telerobots were accessible only to trained and trusted experts through dedicated communication channels. This chapter will describe relevant network technology, the history of networked robots as it evolves from teleoperation to cloud robotics, properties of networked robots, how to build a networked robot, example systems. Later in the chapter, we focus on the recent progress on cloud robotics, and topics for future research.

44.1 Overview and Background	1109
44.2 A Brief History	1110
44.2.1 Networked Teleoperation	1110
44.2.2 Cloud Robotics and Automation ..	1111
44.3 Communications and Networking	1112
44.3.1 The Internet	1113
44.3.2 Wired Communication Links	1113
44.3.3 Wireless Links	1114
44.3.4 Video and Audio Transmission Standards	1114
44.4 Properties of Networked Robots	1115
44.4.1 Overall Structure	1115

44.1 Overview and Background

As illustrated in Fig. 44.1, the field of networked robots locates at the intersection between two exciting fields: robotics and networking. Similarly, teleoperation (Chap. 43) and multiple mobile robot systems (Chap. 51) also find their overlaps in the intersection. The primary concerns of the teleoperation are stability and time delay. Multiple mobile robot systems concerns coordination and planning of autonomous robots and sensors communicating over local networks. *The subfield of Networked Robots focuses on the robot system architectures, interfaces, hardware, software, and*

applications that use networks (primarily the Internet/Cloud).

By 2012, several hundred networked robots have been developed and put online for public use. Many papers have been published describing these systems and a book on this subject by *Goldberg and Siegwart* is available [44.1]. Updated information about new research and an archive/survey of networked robots is available on the website of the [IEEE](#) technical committee on networked robots, which fosters research in this area [44.2].

Fig. 44.1 Relationship between the subjects of networked robots (Chap. 44, this chapter), teleoperation (Chap. 43), and multiple mobile robot systems (Chap. 53) ►

The rest of the chapter is organized as follows: we first review the history and related work in Sect. 44.2. In Sect. 44.3, we review network and communication technology to provide necessary background for the following two main Sects. 44.4 and 44.5. Section 44.4 focuses on traditional networked robots while Sect. 44.5 summarize the new development in cloud

robotics. Section 44.6, we conclude the chapter with recent applications and future directions.

44.2 A Brief History

Networked robots have their root in teleoperation systems, which started as remotely controlled devices. However, thanks to the recent evolution of the Internet and wireless networks, networked robots quickly expand their scope from the traditional master–slave teleoperation relationship to an integration of robots, human, agents, off-board sensors, databases, and clouds over the globe. To review the history of networked robots, we trace back to the root: remotely controlled devices.

44.2.1 Networked Teleoperation

Like many technologies, remotely controlled devices were first imagined in science fiction. In 1898, *Nicola Tesla* [44.3] demonstrated a radio-controlled boat in New York’s Madison Square Garden. The first major experiments in teleoperation were motivated by the need to handle radioactive materials in the 1940s. *Goertz* and *Thompson* demonstrated one of the first bilateral simulators in the 1950s at the Argonne National Laboratory [44.4]. Remotely operated mechanisms have been designed for use in inhospitable environments such as undersea [44.5] and space exploration [44.6]. At General Electric, *Mosher* [44.7] developed a two-arm teleoperator with video cameras. Prosthetic hands were also applied to teleoperation [44.8]. More recently, teleoperation is being considered for medical diagnosis [44.9], manufacturing [44.10] and micromanipulation [44.11]. See Chap. 43 and the book from *Sheridan* [44.12] for excellent reviews on teleoperation and telerobotics research.

The concept of hypertext (linked references) was proposed by Vannevar Bush in 1945 and was made possible by the subsequent developments in computing and networking. In the early 1990s, Berners-Lee introduced the hypertext transmission protocol (HTTP). A group of students led by Marc Andreessen developed an open

source version of the first graphical user interface, the *Mosaic* browser, and put it online in 1993. The first networked camera, the predecessor of today’s *webcam*, went online in November 1993 [44.13]

Approximately nine months later, the first networked telerobot went online. The *Mercury Project* combined an IBM industrial robot arm with a digital camera and used the robot’s air nozzle to allow remote users to excavate for buried artifacts in a sandbox [44.14, 15]. Working independently, a team led by *Taylor* and *Trevelyan* at the University of Western Australia demonstrated a remotely controlled six-axis telerobot in September 1994 [44.16, 17]. These early projects pioneered a new field of networked telerobots. See [44.18–26] for other examples.

Networked telerobots are a special case of *supervisory control* telerobots, as proposed by *Sheridan* and his colleagues [44.12]. Under supervisory control, a local computer plays an active role in closing the feedback loop. Most networked robotics are type (c) supervisory control systems (Fig. 44.2).

Although a majority of networked telerobotic systems consist of a single human operator and a single robot [44.27–34], *Chong* et al. [44.35] propose a useful taxonomy: single operator single robot (**SOSR**), single operator multiple robot (**SOMR**) [44.36, 37], multiple operator single robot (**MOSR**), and multiple operator multiple robot (**MOMR**) [44.38, 39] (VIDEO 81, VIDEO 84). These frameworks greatly extend system architecture of networked robots. In fact, human operators can often be replaced with autonomous agents, off-board sensors, expert systems, and programmed logics, as demonstrated by *Xu* and *Song* [44.40] and *Sanders* et al. [44.41]. The extended networked connectivity also allows us to employ techniques such as crowd sourcing and collaborative control for demanding applications such as nature observation and environment monitoring [44.42, 43]. Hence, networked teler-

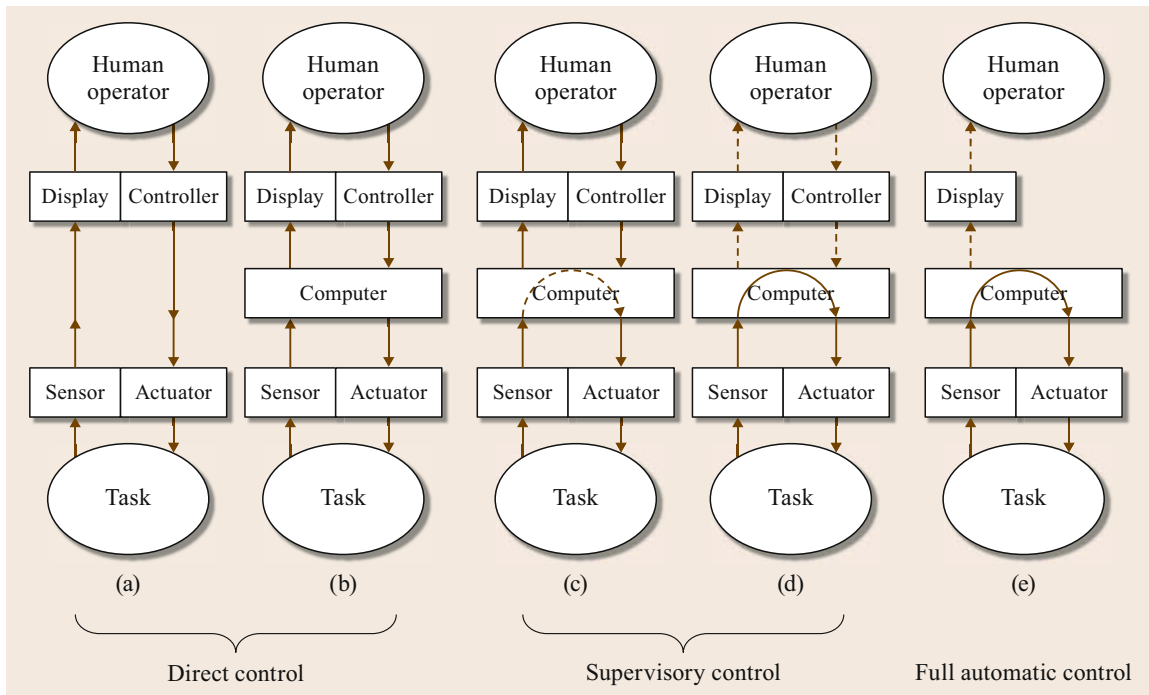

Fig. 44.2 A spectrum of teleoperation control modes adapted from *Sheridan's* text (after [44.12]). We label them (a–e), in order of increasing robot autonomy. At the far left would be a mechanical linkage where the human directly operates the robot from another room through sliding mechanical bars, and on the far right is the system where the human role is limited to observation/monitoring. In (c–e), the dashed lines indicated that communication may be intermittent

obots fully evolve into networked robots: an integration of robots, humans [44.44], computing power, off-board sensing, and databases over the Internet.

The last 18 years (1994–2012) witnessed the extensive development in networked robots. New systems, new experiments, and new applications go well beyond traditional fields such as defense, space, and nuclear material handling [44.12] that motivated teleoperation in early 1950s. As the Internet introduces universal access to every corner of life, the impact of networked robots becomes broader and deeper in modern society. Recent applications range from education, industry, commercial, health care, geology, environmental monitoring, to entertainment, and arts.

Networked robots provide a new medium for people to interact with remote environment. A networked robot can provide more interactivity beyond what a normal videoconferencing system. The physical robot not only represents the remote person but also transmits multi-modal feedback to the person, which is often referred as *telepresence* in the literature [44.30]. *Paulos et al.'s* Personal ROving Presence (PRoP) robot [44.45], *Jouppi and Thomas' Surrogate robot* [44.30], *Takayama et al.'s Texai* [44.46], and *Lazewatsky and Smart's* inexpensive platform [44.47] are representative work.

Networked robots have great potential for education and training. In fact, one of the earliest networked telerobot systems [44.48] originates from the idea of a remote laboratory. Networked telerobots provide universal access to the general public, who may have little to no knowledge of robots, with opportunities to understand, learn, and operate robots, which were expensive scientific equipment limited to universities and large corporate laboratories before. Built on networked telerobots, online remote laboratories [44.49, 50] greatly improves distance learning by providing an interactive experience. For example, teleoperated telescopes help students to understand astronomy [44.51]. Teleoperated microscope [44.52] helps student to observe micro-organisms. The Tele-Actor project [44.53] allows a group of students to remotely control a human tele-actor to visit environments that are normally not accessible to them such as clean-room environments for semiconductor manufactory facility and deoxyribonucleic acid (DNA) analysis laboratories.

44.2.2 Cloud Robotics and Automation

Recent development of cloud computing provide new means and platform for networked robots. In

2010, *Kuffner* at Google introduced the term *Cloud robotics* [44.54] to describe a new approach to robotics that takes advantage of the Internet as a resource for massively parallel computation and real-time sharing of vast data resources. The Google autonomous driving project exemplifies this approach: the system indexes maps and images that are collected and updated by satellite, Streetview, and crowdsourcing from the network to facilitate accurate localization. Another example is Kiva Systems new approach to warehouse automation and logistics using large numbers of mobile platforms to move pallets using a local network to coordinate planforms and update tracking data. These are just two new projects that build on resources from the Cloud. Steve Cousins of Willow Garage aptly summarized the idea: *No robot is an island*. Cloud robotics recognizes the wide availability of networking, incorporates elements of open-source, open-access, and crowdsourcing to greatly extend earlier concepts of *Online Robots* [44.1] and *Networked Robots* [44.55, 56].

The Cloud has been used as a metaphor for the Internet since the inception of the World Wide Web in the early 1990s. As of 2012, researchers are pursuing a number of cloud robotics and automation projects [44.57, 58]. New resources range from software architectures [44.59–62] to computing resources [44.63]. The RoboEarth project [44.64] aims to develop [44.65]:

a World Wide Web for robots: a giant network and database repository where robots can share information and learn from each other about their behavior and their environment.

Cloud robotics and automation is related to concepts of the *Internet of Things* [44.66] and the *Industrial Internet*, which envision how radio-frequency identification (RFID) and inexpensive processors can be incorporated into a vast array of objects from inventory items to household appliances to allow them to communicate and share information.

44.3 Communications and Networking

Below is a short review of relevant terminologies and technologies on networking. For details, see the texts by [44.67].

A communication network includes three elements: *links*, *routers/switchers*, and *hosts*. Links refer to the physical medium that carry bits from one place to another. Examples of links include copper or fiber-optic cables and wireless (radio frequency or infrared) channels. Switches and routers are hubs that direct digital information between links. Hosts are communication end points such as browsers, computers, and robots.

Networks can be based in one physical area (local-area network, or LAN), or distributed over wide distances (wide-area network, or WAN). Access control is a fundamental problem in networking. Among a variety of methods, the *ethernet* protocol is the most popular. Ethernet provides a broadcast-capable multi-access LAN. It adopts a carrier-sense multiple-access (CSMA) strategy to address the multiple-access problem. Defined in the IEEE 802.x standard, CSMA allows each host to send information over the link at any time. Therefore, collisions may happen between two or more simultaneous transmission requests. Collisions can be detected either by directly sensing the voltage in the case of wired networks, which is referred to as collision detection (CSMA/CD), or by checking the time-out of an anticipated acknowledgement in wireless networks, which is referred to as collision avoidance (CSMA/CA). If a collision is detected, both/all senders randomly back off a short period of time before retrans-

mitting. CSMA has a number of important properties: (1) it is a completely decentralized approach, (2) it does not need clock synchronization over the entire network, and (3) it is very easy to implement. However, the disadvantages of CSMA are: (1) the efficiency of the network is not very high and (2) the transmission delay can change drastically.

As mentioned previously, LANs are interconnected with each other via routers/switchers. The information transmitted is in packet format. A packet is a string of bits and usually contains the source address, the destination address, content bits, and a checksum. Routers/switchers distribute packets according to their routing table. Routers/switchers have no memory of packets, which ensures scalability of the network. Packets are usually routed according to a first-in first-out (FIFO) rule, which is independent of the application. The packet formats and addresses are independent of the host technology, which ensures extensibility. This routing mechanism is referred to as packet switching in the networking literature. It is quite different from a traditional telephone network, which is referred to as circuit switching. A telephone network is designed to guarantee a dedicated circuit between a sender and a receiver once a phone call is established. The dedicated circuitry ensures communication quality. However, it requires a large number of circuits to ensure the quality of service (QOS), which leads to poor utilization of the overall network. A packet-switching network cannot guarantee dedicated bandwidth for each indi-

vidual pair of transmissions, but it improves overall resource utilization. The Internet, which is the most popular communication media and the infrastructure of networked telerobots, is a packet-switching network.

44.3.1 The Internet

The creation of the Internet can be traced back to US Department of Defense's (DOD) APRA NET network in the 1960s. There are two features of the APRA NET network that enabled the successful evolution of the Internet. One feature is the ability for information (packets) to be rerouted around failures. Originally, this was designed to ensure communication in the event of a nuclear war. Interestingly, this dynamic routing capability also allows the topology of the Internet to grow easily. The second important feature is the ability for heterogeneous networks to interconnect with one another. Heterogeneous networks, such as X.25, G.701, ethernet, can all connect to the Internet as long as they can implement the Internet protocol (IP). The IP is media, operating system (OS), and data rate independent. This flexible design allows a variety of applications and hosts to connect to the Internet as long as they can generate and understand IP.

Figure 44.3 illustrates a four-layer model of the protocols used in the Internet. On the top of the IP, we have two primary transport layer protocols: the transmission control protocol (TCP) and the user data protocol (UDP). TCP is an end-to-end transmission control protocol. It manages packet ordering, error control, rate control, and flow control based on packet round-trip time. TCP guarantees the arrival of each packet. However, excessive retransmission of TCP in a congested network may introduce undesirable time delays in a net-

worked telerobotic system. UDP behaves differently; it is a broadcast-capable protocol and does not have a retransmission mechanism. Users must take care of error control and rate control themselves. UDP has a lot less overhead compared to TCP. UDP packets are transmitted at the sender's preset rate and the rate is changed based on the congestion of a network. UDP has great potential, but it is often blocked by firewalls because of a lack of a rate control mechanism. It is also worth mentioning that the widely accepted term TCP/IP refers to the family of protocols that build on IP, TCP, and UDP.

In the application layer of the Internet protocols, the HTTP is one of the most important protocols. HTTP is the protocol for the World Wide Web (WWW). It allows the sharing of multimedia information among heterogeneous hosts and OSs including text, image, audio, and video. The protocol has significantly contributed to the boom of the Internet. It also changes the traditional client/server (C/S) communication architecture to a browser/server (B/S) architecture. A typical configuration of the B/S architecture consists of a web server and clients with web browsers. The web server projects the contents in hypertext markup language (HTML) format or its variants, which is transmitted over the Internet using HTTP. User inputs can be acquired using the common gateway interface (CGI) or other variants. The B/S architecture is the most accessible because no specialized software is needed at the client end.

44.3.2 Wired Communication Links

Even during peak usage, the network backbones of the Internet often run at less than 30% of their overall capacity. The average backbone utilization is around 15–20%. The primary speed limitation for the Internet

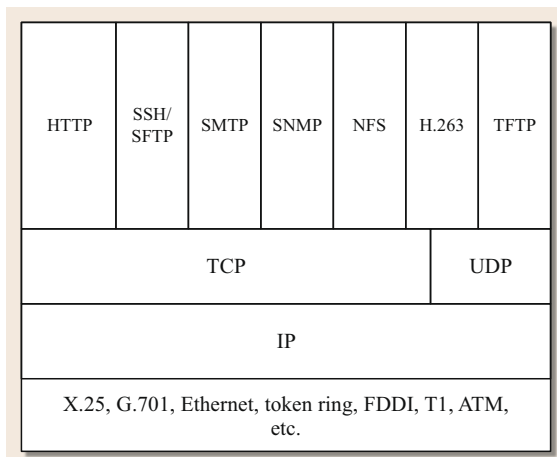

Fig. 44.3 A four-layer model of Internet protocols (after [44.67])

Table 44.1 Last-mile Internet speed by wired connection type (if not specified, the downstream transmission and the upstream transmission share the same bandwidth)

Types	Bits per second
Dialup modem (V.92)	Up to 56 K
Integrated services digital network (ISDN)	64–160 K for BRI, up to 2048 K for PRI
High data rate digital subscriber line (HDSL)	Up to 2.3 M duplex on two twisted-pair lines
Asymmetric digital subscriber line (ADSL)	1.544–24.0 M downstream, 0.5–3.3 M upstream
Cable modem	2–400 M downstream, 0.4–108 M upstream
Fiber to the home (FTTH)	0.005–1 G downstream, 0.002–1 G upstream
Direct Internet II node	1.0–10.0 G

Table 44.2 Survey of wireless technologies in terms of bit rate and range

Types	Bit rate (bps)	Band (Hz)	Range (m)
Zigbee (802.15.4)	20–250 K	868–915 M/2.4 G	50
Bluetooth	732 K–3.0 M	2.4 G	100
3G HSPA	400 K–14.0 M	≤ 3.5 G	N/A
HSPA+	5.76 M–44.0 M	≤ 3.5 G	N/A
LTE	10 M–300 M	≤ 3.5 G	N/A
WiFi (802.11a,b,g,n)	11–600 M	2.4 G/5 G	100

is the *last mile*, the link between clients and their local Internet service providers (ISP).

Table 44.1 lists typical bit rates for different connection types. It is interesting to note the asymmetric speeds in many cases, where upstream bit rate (from the client to the Internet), are far slower than downstream bit rates (from the Internet to the client). These asymmetries introduce complexity into the network model for teleoperation. Since the speed difference between the slowest modem link and the fastest Internet II node is over 10 000, designers of a networked telerobotic system should anticipate a large variance of communication speeds.

44.3.3 Wireless Links

Table 44.2 compares the speed, band, and range of wireless standards as of 2012. Increasing bit rate and communication range requires increasing power. The amount of radio frequency (RF) transmission power required over a distance d is proportional to d^k , where $2 \leq k \leq 4$ depending on the antenna type. In Table 44.2, Bluetooth and Zigbee are typical low-power transmission standards that are good for short distances. HSPA+ and LTE are commercially marketed as the 4G cellphone network.

By providing high-speed connectivity at low cost, WiFi is the most popular wireless standard in 2012. Its range is approximate 100 m line of sight and the WiFi wireless network usually consists of small-scale interconnected access points. The coverage range usually limits these networks to an office building, home, and other indoor environments. WiFi is a good option for indoor mobile robots and human operators. If the robot needs to navigate in the outdoor environment, the 3G or 4G cellphone network can provide the best coverage available. Although obvious overlap exists among wireless standards in coverage and bandwidth, there are two import issues that have not been covered by Table 44.2. One is mobility. We know that, if an RF source or receiver is moving, the corresponding Doppler effect causes a frequency shift, which could cause problems in communication. WiFi is not designed for fast-moving hosts. 3G HSPA cellphone allows the host to move at a vehicle speed under 120 km/h. However, LTE allows

the host to move at a speed of 350 or 500 km/h, which even works for high-speed trains.

Long range wireless links often suffer from latency problem, which may drastically decreases system performer as discussed in Chap. 43. One may notice that we did not list satellite wireless in Table 44.2 because the long latency (0.5–1.7 s) and high price makes it difficult to be useful for robots. The large antenna size and high power consumption rate also limits its usage in mobile robots. In fact, the best option for long range wireless is LTE. LTE is designed with a transmission latency of less that 4 ms whereas 3G HSPA cellphone networks have a variable latency of 10–500 ms.

44.3.4 Video and Audio Transmission Standards

In networked robots systems, the representation of the remote environment is often needed to be delivered to online users in video and audio format. To deliver video and audio over the Internet, raw video and audio data from camera optical sensor and microphone must be compressed according to different video and audio compression standards to fit in the limited network bandwidth. Due to lack of bandwidth and computing power to encode streaming video, most early systems only transmit periodic snapshots of the remote scene in JPEG format at limited frame rate, i. e., 1–2 frames per second or less. Audio was rarely considered in the early system design. The rudimentary video delivery methods in the early system were mostly implemented using HTML and JavaScript to reload the JPEG periodically.

Today, the expansion of HTML standards allow web browsers to employ plug-ins as the client end of streaming video. HTML5 even natively supports video decoding. Therefore, the server end of recent systems often employs streaming server software, such as Adobe Flash Media Encoder, Apple Quick Time Streaming Server, Oracle Java Media Framework, Helix Media Delivery Platform, Microsoft DirectX, SkypeKit, etc., to encode and deliver video. These streaming video sever packages often provide easy-to-use software development kit (SDK) to facilitate system integration.

It is worth noting that these different software packages are just different implementations of video/audio

Table 44.3 A comparison of existing videostreaming standards for the same resolution under the same fixed bandwidth (FMBT represents buffering time settings that would not significantly decrease compression ratio or video quality.)

Standards	Feasible minimum buffering time (FMBT)	Framerate
MJPEG	Zero (< 10 ms)	Low
MPEG2	Variable (i. e., 50 ms – video length), 2–10 s are common	Moderate
H.263+	< 300 ms	High
H.264/ MPEG4-AVC	Zero (< 10 ms)	Highest

streaming protocols. Not every protocol is suitable for networked robots. Some protocols are designed to deliver video on demand while others are designed for live streaming for videoconferencing purposes. Networked robots use real-time video as feedback information, which imposes strict requirements in latency and bandwidth similar to those of videoconferencing. One way latency of more than 150 ms can significantly degrade telepresence and hence the performance of the human operator.

Latency is often caused by bandwidth and video encoding/decoding time. Since audio data amount is negligible when comparing to that video data. We will

focus the discussion on video compression standards. There is always a tradeoff between frame rate and resolution for a given bandwidth. There is also a tradeoff between compression ratio and computation time for a given central processing unit (CPU). The computation time includes both CPU time and data-buffering time at both client and server ends. Video encoding is a very computationally intensive task. A long computation period introduces latency and significantly impair the system performance. It is possible to use hardware to cut down the computation time but not the data-buffering time, which are controlled by the video encoder.

There are many standards and protocols available but most of them are just variations of MJPEG, MPEG2, H.263, and MPEG4-AVC/H.264. We compare those standards in Table 44.3. Note that the comparison is qualitative and may not be the most accurate due to the fact that each video encoding standard has many parameters that affect the overall buffering time.

From networked robot point of view, the buffering time determines the latency and the frame rate determines the responsiveness of the system. An ideal videostream should have both high frame rate and low buffering time. But if both cannot be achieved at the same time, low latency is preferred. From Table 44.3, H.264/MPEG4-AVC clearly outperforms other competitors and is the most popular video compression method.

44.4 Properties of Networked Robots

Networked robots have the following properties:

- The physical world is affected by a device that is locally controlled by a network *server*, which connects to the Internet to communicate with remote human users, databases, agents, and off-board sensors, which are referred to as *clients* of the system.
- Human decision making capability is often an integral part of the system. If so, humans often access the robot via web browsers, such as Internet Explorer or Firefox, or apps in mobile device. As of 2012, the standard protocol for network browsers is the hypertext transfer protocol (HTTP), a stateless transmission protocol.
- Most networked robots are continuously accessible (online), 24 h a day, 7 days a week.
- Networks may be unreliable or have different speed for clients with different connections.
- Since hundreds of millions of people now have access to the Internet, mechanisms are needed to handle client authentication and contention. System

security and privacy of users are important in the networked robots.

- Input and output for human users for networked robots are usually achieved with the standard computer screen, mouse, and keyboard.
- Clients may be inexperienced or malicious, so online tutorials and safeguards are generally required.
- Additional sensing, databases, and computing resources may be available over the network.

44.4.1 Overall Structure

As defined by *Mason*, *Peshkin*, and others [44.68, 69], in *quasistatic* robot systems, accelerations, and inertial forces are negligible compared to dissipative forces. In quasistatic robot systems, motions are often modeled as transitions between discrete atomic *configurations*.

We adopt a similar terminology for networked telerobots. In quasistatic telerobotics (QT), robot dynamics and stability are handled locally. After each atomic motion, a new state report is presented to the remote user,

who sends back an atomic command. The atomic state describes the status of the robot and its corresponding environment. Atomic commands refer to human directives, which are desired robotic actions.

Several issues arise:

- *State-command presentation*: How should state and available commands be presented to remote human operators using the two-dimensional (2-D) screen display?
- *Command execution/state generation*: How should commands be executed locally to ensure that the desired state is achieved and maintained by the robot?
- *Command coordination*: How should commands be resolved when there are multiple human operators and/or agents? How to synchronize and aggregate commands issued by users/agents with different network connectivity, background, responsiveness, error rate, etc., to achieve the best possible system performance?
- *Virtual Fixture: Error prevention and state correction*: How should the system prevent the wrong commands that may lead the robot to collision or other undesirable states?

Before we detail these issues, let us walk through how to build a minimum networked robot system.

Fig. 44.4 Typical system architecture for a networked telerobot

Fig. 44.5 A sample software architecture of a networked telerobot

A reader can follow the below example to build his/her own networked robot system as well as understand challenges in the issues.

44.4.2 Building a Networked Robot System

This minimal system is a networked telerobotic system which allows a group of users to access a robot via web browsers. As illustrated in Fig. 44.4, a typical or minimal networked telerobotic system typically includes three components:

- *Users*: Anyone with an Internet connection and a web browser or equivalent apps that understand [HTTP](#).
- *Web server*: A computer running a web server software.
- *Robot*: A robot manipulator, a mobile robot, or any device that can modify or affect its environment.

Users access the system via their web browsers. Any web browser that is compatible with W3C's [HTML](#) standard can access a web server. In 2012, the most popular web browsers are Microsoft Internet Explorer, Mozilla Firefox, Google Chrome, Apple Safari, and Opera. New browsers and updated versions with new features are introduced periodically. All of these popular browsers issue the corresponding mobile apps to support mobile devices such as Apple iPads, Apple iPhones, and Google Android-based Tablets and smart phones.

A web server is a computer that responds to [HTTP](#) requests over the Internet. Depending upon the operating system of the web server, popular server software packages include Apache and Microsoft Internet Information Services ([IIS](#)). Most servers can be freely downloaded from the Internet.

To develop a networked telerobot, one needs a basic knowledge of developing, configuring, and maintaining web servers. As illustrated in Fig. 44.5, the development requires knowledge of [HTML](#) and at least one local programming languages such as C, C#, [CGI](#), Javascript, Perl, PHP, .Net, or Java.

It is important to consider compatibility with the variety of browsers. Although [HTML](#) is designed to be compatible with all browsers, there are exceptions. For example, Javascript, which is the embedded scripting language of web browsers, is not completely compatible between Internet Explorer and Firefox. One also needs to master the common [HTML](#) components such as forms that are used to accept user inputs, frames that are used to divide the interface into different functional regions, etc. An introduction to [HTML](#) can be found in [44.70].

User commands are usually processed by the web server using **CGI**, the common gateway interface. Most sophisticated methods such as PHP, Java Server Pages (**JSP**), and socket-based system programming can also be used. **CGI** is invoked by the **HTTP** server when the **CGI** script is referred in the uniform resource locator (**URL**). The **CGI** program then interprets the inputs, which is often the next robot motion command, and sends commands to the robot via a local communication channel. **CGI** scripts can be written in almost any programming language. The most popular ones are Perl and C.

A simple networked telerobotic system can be constructed using only **HTML** and **CGI**. However, if the robot requires a sophisticated control interface, advanced plug-ins such as Java Applet, Silver Light, or Flash, are recommended. These plug-ins run inside the web browser on the client's computer. Information about these plug-ins can be found at home pages of Oracle, Microsoft, and Adobe, respectively. Java applet is highly recommended because it is the most widely supported by different browsers. Recently, the fast adoption of **HTML5** also provide a new long term solution to solve the compatibility issue.

Most telerobotic systems also collect user data and robot data. Therefore, database design and data processing program are also needed. The most common used databases include MySQL and PostgreSQL. Both are open-source databases and support a variety of platforms and operation systems. Since a networked telerobotic system is online 24 h a day, reliability is also an important consideration in system design. Website security is critical. Other common auxiliary developments include online documentation, online manual, and user feedback collection.

It is not difficult to expand this minimal networked telerobotic system into a full-fledged networked robot system. For example, some users can be replaced by agents that runs 24 h a day and 7 days a week to monitor system states and co-perform tasks with humans or take over the system when nobody is online. These agents can be implemented using cloud computing. Such extensions are usually based on the need of the task.

44.4.3 State-Command Presentation

To generate a correct and high-quality command depends on how effectively the human operator understands the state feedback. The state-command presentation contains three subproblems: the **2-D** representation of the true robot state (state display), the assistance provided by the interface to generate new commands (spatial reasoning), and the input mechanism.

State Displays

Unlike traditional point-to-point teleoperation, where specialized training and equipment are available to operators, networked telerobots offer wide access to the general public. Designers cannot assume that operators

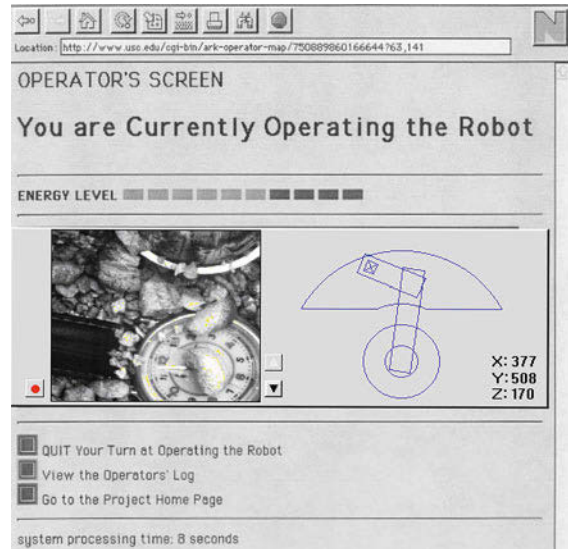

Fig. 44.6 Browser's view of the first networked telerobot interface (after [44.55]). The schematic at *lower right* gives an overhead view of position of the four-axis robot arm (with the camera at the end marked with X), and the image at the *lower left* indicates the current view of the camera. The *small button marked with a dot at the left* directs a 1 s burst of compressed air into the sand below the camera. The Mercury Project was online from August 1994 to March 1995

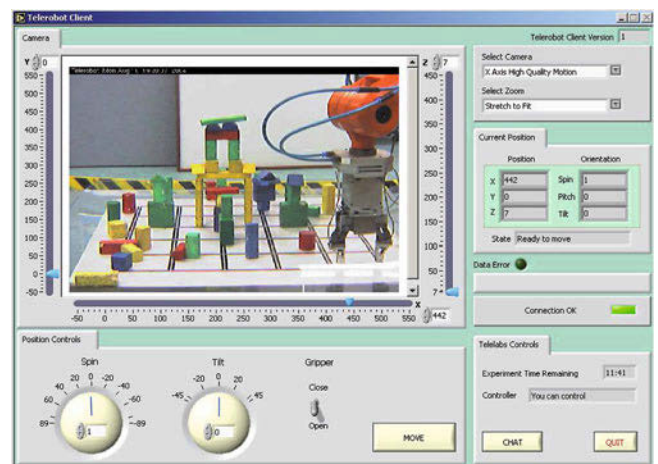

Fig. 44.7 Browser interface to the Australian networked telerobot which was a six-axis arm that could pick up and move blocks (after [44.17])

have any prior experience with robots. As illustrated in Fig. 44.6, networked telerobotic systems must display the robot state on a 2-D screen display.

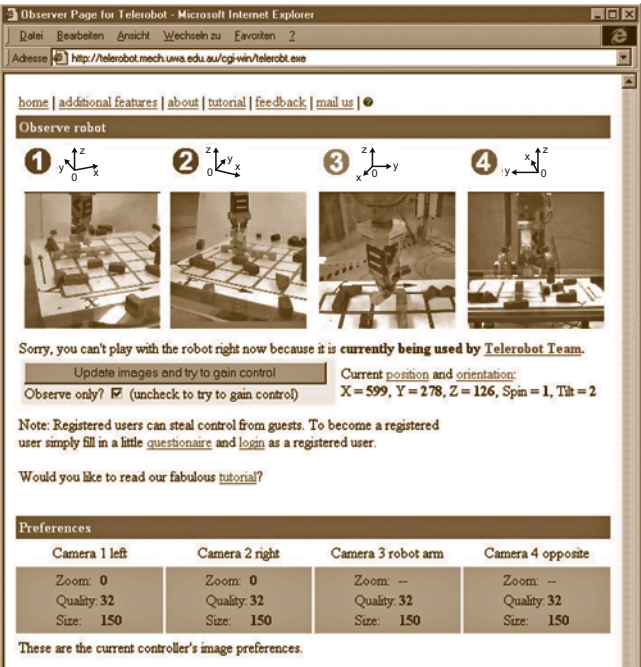

Fig. 44.8 Use of a multicamera system for multiviewpoint state feedback (after [44.71])

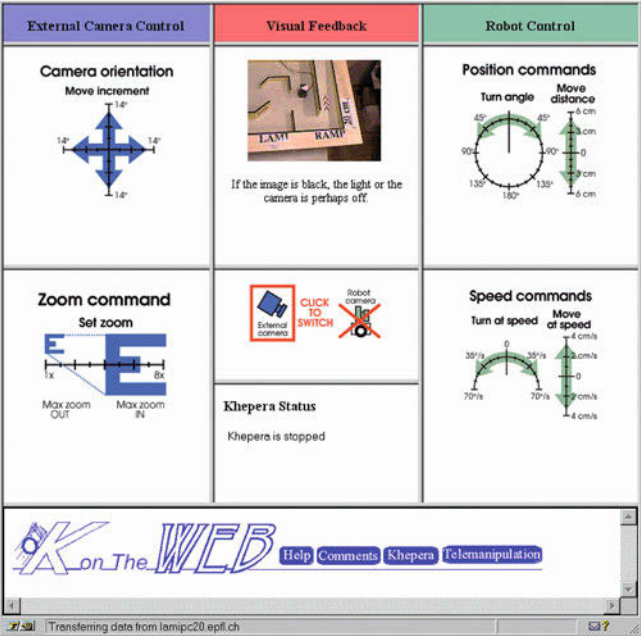

Fig. 44.9 Camera control and mobile robot control in Patrick Saucy and Francesco Mondada's Khep on the web project

The states of the teleoperated robot are often characterized in either world coordinates or robot joint configuration, which are either displayed in numerical format or through a graphical representation. Figure 44.6 lists robot XYZ coordinates on the interface and draws a simple 2-D projection to indicate joint configurations. Figure 44.7 illustrates another example of teleoperation interface that was developed by Taylor and Trevelyan [44.48]. In this interface, XYZ coordinates are presented in a sliding bar near the video window.

The state of the robot is usually displayed in a 2-D view as shown in Figs. 44.6 and 44.7. In some systems, multiple cameras can help the human operator to understand the spatial relationship between the robot and the objects in the surrounding environment. Figure 44.8 shows an example with four distinct camera views for a six-degree-of-freedom industrial robot.

Figure 44.9 demonstrate an interface with a pan-tilt-zoom robotic camera. The interface in Fig. 44.9 is designed for a mobile robot.

More sophisticated spatial reasoning can eliminate the need for humans to provide low-level control by automatically generating a sequence of commands after it receives task-level commands from the human operator. This is particularly important when the robotic system is highly dynamic and requires a very fast response. In this case, it is impossible to ask the human to generate intermediate steps in the robot control; for example, Belousov et al. adopt a shared autonomy model to direct a robot to capture a moving rod [44.28] as shown in Fig. 44.10. Fong and Thorpe [44.72] summarize vehicle teleoperation systems that utilize these supervisory control techniques. Su and Luo developed an incremental algorithm for better translation of the intention and motion of operators into remote robot action commands [44.33].

The fast development of sensing and display technology makes it possible to visualize robot and environment states in three-dimensional (3-D) displays or generate synthetic eco-centric views (a.k.a. third person views) (VIDEO 82). To achieve that, it often requires the robot to be equipped with multiple cameras and laser range finders to quickly reconstruct the remote environment [44.73, 74]. Sometimes, the reconstructed sensory information can be superimposed on priorly known 3-D information to form an augmented reality. This kind of display can drastically increase telepresence and performance.

Human Operator Input

Most networked telerobotic systems only rely on mouses and keyboards for input. The design problem is what to click on in the interface. Given the fact that user commands can be quite different, we need to adopt

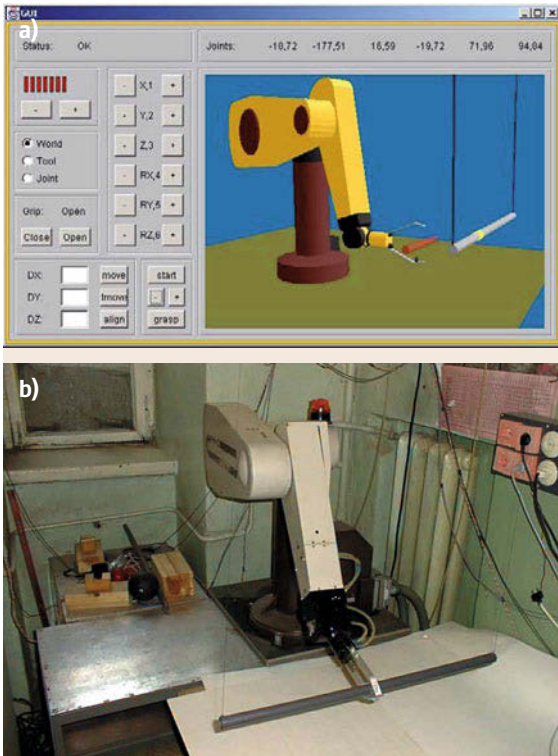

Fig. 44.10a,b A web-based teleoperation system that allows a robot to capture a fast-moving rod. (a) User interface, and (b) system setup (after [44.28])

an appropriate interface for inputs; for example, inputs could be Cartesian XYZ coordinates in world coordinate system or robot configurations in angular joint configurations.

For angular inputs, it is often suggested to use a round dial as a control interface, as illustrated in bottom left of Fig. 44.7 and the right-hand side of Fig. 44.9. For linear motion in Cartesian coordinate, arrows operated by either mouse clicks or the keyboard are often suggested. Position and speed controls are often needed, as illustrated in Fig. 44.9. Speed control is usually controlled by mouse clicks on a linear progress bar for translation and a dial for rotation.

The most common control type is the position control. The most straightforward way is to click on the video image directly. To implement the function, the software needs to translate the 2-D click inputs into three-dimensional (3-D) world coordinates. To simplify the problem, the system designer usually assumes that the clicked position is on a fixed plane; for example, a mouse click on the interface of Fig. 44.6 assumes the robot moves on the X - Y plane. The combination of a mouse click on the image can also allow abstract task-level command. The example in Fig. 44.12 uses mouse

clicks to place votes on an image to generate a command that directs a robot to pick up a test agent at the task level.

44.4.4 Command Execution/State Generation

When a robot receives a command, it executes the command and a new state is generated and transmitted back to the human operator. However, commands may not arrive in time or may get lost in transmission. Also, because users are often inexperienced, their commands may contain errors. Over the limited communication channel, it is impossible to ask the human to control the manipulator directly. Computer vision, laser range finder, local intelligence, and augmented-reality-based displays [44.74] are required to assist the human operator.

Belousov et al. demonstrated a system that allowed a web user to capture a fast rod that is thrown at a robot manipulator [44.28]. The rod is on bifilar suspension, performing complicated oscillations. Belousov et al. designed a shared-autonomy control to implement the capture. First, an operator chooses the desired point for capture on the rod and the capture instant using a 3-D online virtual model of the robot and the rod. Then, the capturing operation is performed automatically using a motion prediction algorithm that is based on the rod's motion model and two orthogonal camera inputs, which perceive the rod's position locally in real time.

This *shared autonomy* approach is often required when the task execution requires much faster response than the Internet can allow. Human commands have to remain at the task level instead of directing the movements of every actuators. The root of this approach can be traced back to the *Tele-Autonomous* concept proposed by Conway et al. [44.75] in 1990. In this paper, two important notions including time clutch and position clutches are introduced to illustrate the shared autonomy approach. The time clutch disengages the time synchronization between the human operator and the robot. The human operator verifies his/her commands on a predictive display before sending a set of verified commands to remote robots. The robot can then optimize the intermediate trajectory proposed by the human operator and disengage the position correspondence, which is referred to as the position clutch. Recent work [44.76] uses the similar idea to guide load-haul-dump vehicles in the underground mines by combining human inputs with tunnel following behavior.

44.4.5 Virtual Fixtures

Due to time delay, lack of background, and possible malicious behavior, human errors are inevitably introduced

to system from time to time. Erroneous states may be generated from the incorrect commands. If unchecked, robots or objects in the environment may be damaged. Sometimes, users may have good intention but are not able to generate accurate commands to control the robot remotely. For example, it is hard to generate a set of commands to direct a mobile robot to move along the wall and maintain a distance of 1 m to the wall at the same time.

Virtual fixtures are designed to cope with these challenges in teleoperation tasks. Proposed by Rosenberg [44.77], virtual fixtures are defined as an overlay of abstract sensory information on a robot workspace in order to improve the telepresence in a telemanipulation task. To further explain the definition, Rosenberg uses a ruler as an example. It is very difficult for a human to draw a straight line using bare hands. However, if a ruler, which is a physical fixture, is provided, then the task becomes easy. Similar to a physical fixture, a virtual fixture is designed to guide robot motion through some fictitious boundaries or force fields, such as virtual tubes or surface, generated according to sensory data. The virtual fixtures are often implemented using control laws [44.78, 79] based on a *virtual contact* model.

Virtual fixtures serve for two main purposes: avoiding operation mistakes and guide robots along the designable trajectories. This is also a type of shared autonomy that is similar to that in Sect. 44.4.4 where both the robot and the human share control in the system. Chapter 43 details the shared control scheme. It is worth noting that virtual fixtures should be visualized in the display to help operators understand the robot state to maintain situation awareness. This actually turns the display to *augmented reality* [44.80].

44.4.6 Collaborative Control and Crowd Sourcing

When more than one human is sharing control of the device, command coordination is needed. According to [44.81], multiple human operators can reduce the chance of errors, cope with malicious inputs, utilize operators' different expertise, and train new operators. In [44.82, 83], a collaboratively controlled networked robot is defined as a telerobot simultaneously controlled by many participants, where input from each participant is combined to generate a single control stream.

When group inputs are in the form of direction vectors, averaging can be used as an aggregation mechanism [44.84]. When decisions are distinct choices or at the abstract task level, voting is a better choice [44.53]. As illustrated in Fig. 44.11, Goldberg and Song (VIDEO 83) develop the Tele-Actor sys-

Fig. 44.11 Spatial dynamic voting interface for the Tele-Actor system: the spatial dynamic voting (SDV) interface as viewed by each user. In the remote environment, the Tele-Actor takes images with a digital camera, which are transmitted over the network and displayed to all participants with a relevant question. With a mouse click, each user places a color-coded marker (a *votel* or voting element) on the image. Users view the position of all votels and can change their votel positions based on the group's response. Votel positions are then processed to identify a *consensus region* in the voting image that is sent back to the Tele-Actor. In this manner, the group collaborates to guide the actions of the Tele-Actor (after [44.53])

tem using spatial dynamic voting. The Tele-Actor is a human equipped with an audio/video device and controlled by a group of online users. Users indicate their intentions by positioning their votes on a 320×320 pixel voting image during the voting interval. Votes are collected at the server and used to determine the Tele-Actor's next action based on the most requested region on the voting image [44.85].

Another approach to collaboratively control a networked robot is the employ a optimization framework. Song et al. [44.86, 87] developed a collaboratively controlled camera that allowed many clients to share control of its camera parameters, as illustrated in Fig. 44.12. Users indicate the area they want to view by drawing rectangles on a panoramic image. The algorithm computes an optimal camera frame with respect to the user satisfaction function, which is defined as the frame selection problem [44.88, 89].

Recent work by Xu et al. [44.40, 90] further the optimization framework to *p*-frames that allows multiple cameras to be controlled and coordinated whereas

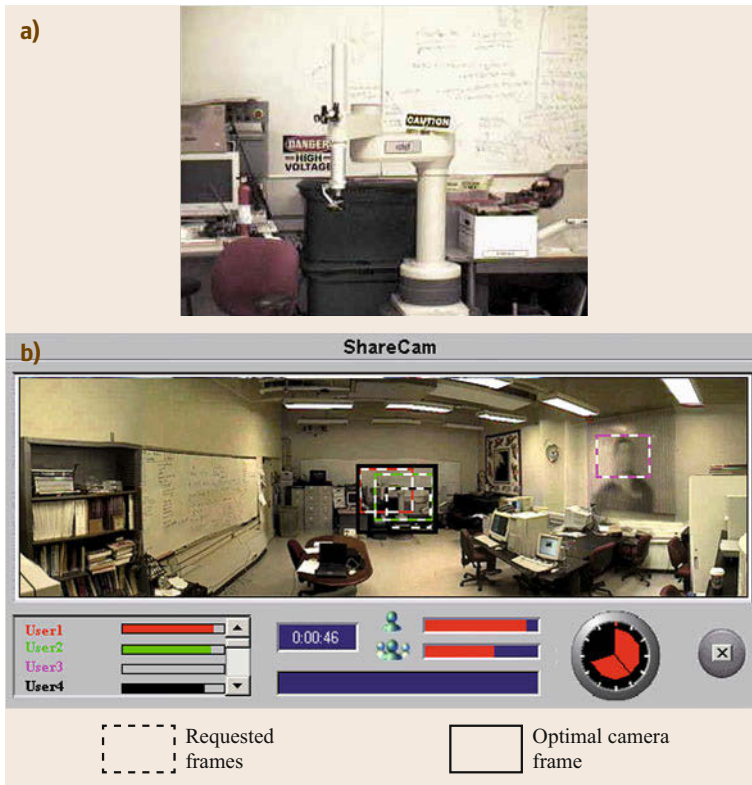

Fig.44.12a,b Frame selection interface (after [44.86]). The user interface includes two image windows. The lower window (b) displays a fixed panoramic image based on the camera's full workspace (reachable field of view). Each user requests a camera frame by positioning a *dashed rectangle* in (b). Based on these requests, the algorithm computes an optimal camera frame (shown with a *solid rectangle*), moves the camera accordingly, and displays the resulting live streaming video image in the upper window (a)

human inputs can also be replaced by autonomous agents and other sensory inputs. These developments have been applied to a recent project, the Collaborative Observatory for Nature Environments (CONE) project [44.91], which aims to design a networked robotic camera system to collect data from the wilderness for natural scientists.

One important issue in collaborative control is the disconnection between individual commands and the robot action, which may lead to the loss of situation awareness, less participation, and eventual system failure. Inspired by engaging power in scoring systems in computer games, Goldberg et al. [44.92] design scoring

mechanism for the collaborative control architecture by evaluating the individual leadership level. The early results show great improvement in the group performance. Furthermore, the recent development of social media, such as Blog and Twitter, can also be employed in the collaborative control to facilitate user interaction in real time, which can make the system more engaging and effective. The resulting new architecture can be viewed as a crowd sourcing [44.42, 93] type approach to networked robots that combines human recognition and decision making capabilities to robot execution at a different scale and depth than a regular teleoperation system.

44.5 Cloud Robotics

As noted earlier, the term *Cloud Robotics* is increasingly common based on advances in what is now called *Cloud Computing*. Cloud Robotics extends what were previously called *Online Robots* [44.1] and *Networked Robots* [44.55, 56]. Cloud computing provides robots with vast resources in computation, memory, programming.

Here we review five ways that cloud robotics and automation can potentially improve robots and automation performance:

1. Providing access to global libraries of images, maps, and object data, eventually annotated with geometry and mechanical properties.

2. Massively parallel computation on demand for demanding tasks like optimal motion planning and sample-based statistical modeling
3. Robot sharing of outcomes, trajectories, and dynamic control policies.
4. Human sharing of *open-source* code, data, and designs for programming, experimentation, and hardware construction.
5. On-demand human guidance (*call centers*) for exception handling and error recovery. Updated information and links are available at [44.94].

44.5.1 Big Data

The term *Big Data* describes data sets that are beyond the capabilities of standard relational database systems, which describes the growing library of images, maps, and many other forms of data relevant to robotics and automation on the Internet. One example is grasping, where online datasets can be consulted to determine appropriate grasps. The Columbia Grasp dataset [44.95] and the MIT KIT object dataset [44.96] are available online and have been widely used to evaluate grasping algorithms [44.97–100].

Related work explores how computer vision can be used with Cloud resources to incrementally learn grasp strategies [44.102, 103] by matching sensor data against 3-D computer-aided drafting (CAD) models in an online database. Examples of sensor data include 2-D image features [44.104], 3-D features [44.105], and 3-D point clouds [44.106]. Google Goggles [44.107], a free network-based image recognition service for mobile devices, has been incorporated into a sys-

tem for robot grasping [44.101] as illustrated in Fig. 44.13.

Dalibard et al. attach *manuals* of manipulation tasks to objects [44.108]. The RoboEarch project stores data related to objects maps, and tasks, for applications ranging from object recognition to mobile navigation to grasping and manipulation (Fig. 44.14) [44.64].

As noted below, online datasets are effectively used to facilitate learning in computer vision. By leveraging Google's 3-D warehouse, [44.109] reduced the need for manually labeled training data. Using community photo collections, [44.110] created an augmented reality application with processing in the cloud.

44.5.2 Cloud Computing

As of 2012, Cloud Computing services like Amazon's EC2 elastic computing engine provide massively parallel computation on demand [44.111]. Examples include Amazon Web Services [44.112] Elastic Compute Cloud, known as EC2 [44.113], Google Compute Engine [44.114], Microsoft Azure [44.115]. These provide a large pool of computing resources that can be rented by the public for short-term computing tasks. These services were originally used primarily by web application developers, but have increasingly been used in scientific and technical high-performance computing (HPC) applications [44.116–119].

Cloud computing is challenging when there are real-time constraints [44.120]; this is an active area of research. However, there are many robotics applications that are not time sensitive such as decluttering a room or precomputing grasp strategies.

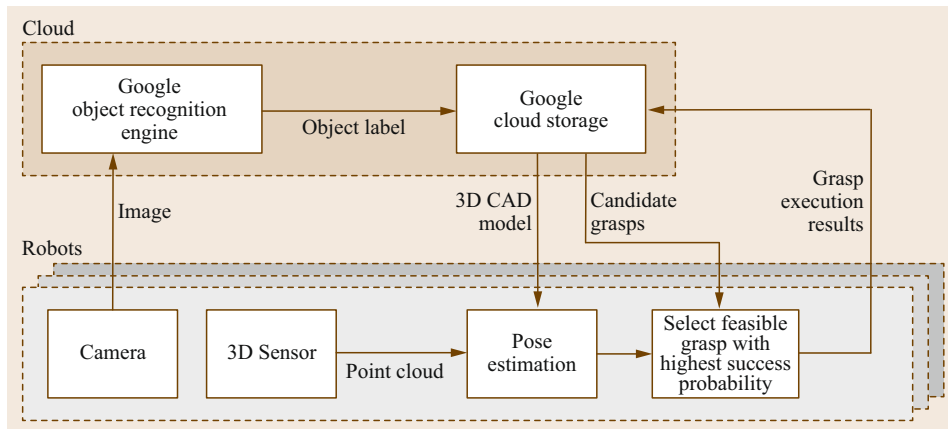

Fig. 44.13 System architecture for cloud-based object recognition for grasping. The robot captures an image of an object and sends via the network to the Google object recognition server. The server processes the image and returns data for a set of candidate objects, each with precomputed grasping options. The robot compares the returned CAD models with the detected point cloud to refine identification and to perform pose estimation, and selects an appropriate grasp. After the grasp is executed, data on the outcome is used to update models in the cloud for future reference (after [44.101])

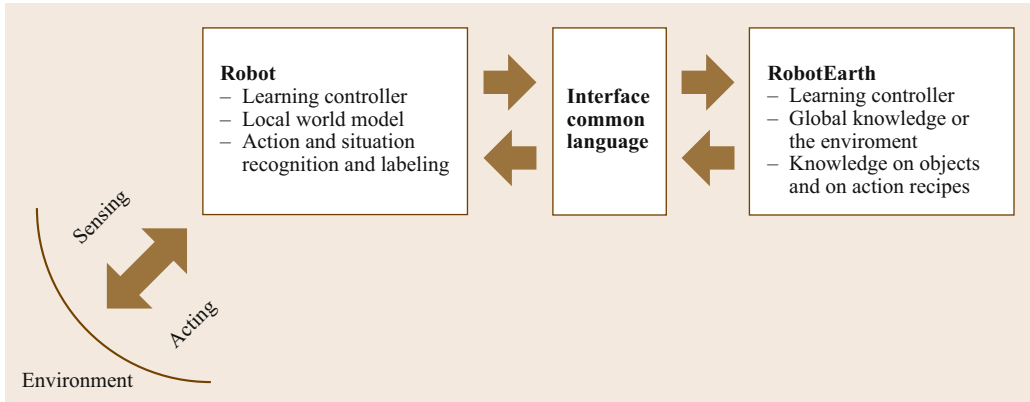

Fig. 44.14 RoboEarth architecture (after [44.64])

There are many sources of uncertainty in robotics and automation [44.121]. Cloud computing allows massive sampling over error distributions and Monte Carlo sampling is *embarrassingly parallel*; recent research in fields as varied as medicine [44.122] and particle physics [44.123] have taken advantage of the cloud. Real-time video and image analysis can be performed in the Cloud [44.109, 124, 125]. Image processing in the cloud has been used for assistive technology for the visually impaired [44.126] and for senior citizens [44.127]. Cloud computing is ideal for sample-based statistical motion planning under uncertainty, where it can be used to explore many possible perturbations in object and environment pose, shape, and robot response to sensors and commands [44.128]. Cloud-based sampling is also being investigated for grasping objects with shape uncertainty [44.129, 130] (Fig. 44.15). A grasp planning algorithm accepts as input a nominal polygonal outline with Gaussian uncertainty around each vertex and the center of mass to compute a grasp quality metric based on a lower bound on the probability of achieving force closure.

44.5.3 Collective Robot Learning

The Cloud allows robots and automation systems to *share* data from physical trials in a variety of envi-

ronments, for example, initial and desired conditions, associated control policies and trajectories, and importantly: data on performance and outcomes. Such data are a rich source for robot learning.

One example is for path planning, where previously generated paths are adapted to similar environments [44.131] and grasp stability of finger contacts can be learned from previous grasps on an object [44.98].

The MyRobots project [44.132] from RobotShop proposes a *social network* for robots [44.133]:

In the same way humans benefit from socializing, collaborating and sharing, robots can benefit from those interactions too by sharing their sensor information giving insight on their perspective of their current state.

44.5.4 Open Source and Open Access

The Cloud facilitates sharing by humans of designs for hardware, data, and code. The success of open-source software [44.134–136] is now widely accepted in the robotics and automation community. A primary example is **ROS**, the Robot Operating System, which provides libraries and tools to help software developers create robot applications [44.137, 138]. **ROS** has also been ported to Android devices [44.139]. **ROS** has be-

Fig. 44.15 A cloud-based approach to geometric shape uncertainty for grasping (after [44.129, 130])

Fig. 44.16 Suckerbot, designed by Tom Tilley of Thailand, a winner of the \$10 Robot Design Challenge (after [44.140])

come a standard akin to Linux and is now used by almost all robot developers in research and many in industry.

Additionally, many simulation libraries for robotics are now open-source, which allows students and researchers to rapidly set up and adapt new systems and share the resulting software. Open-source simulation libraries include Bullet [44.141], a physics simulator originally used for video games, OpenRAVE [44.142] and Gazebo [44.143], simulation environments geared specifically toward robotics, OOPSMP, a motion-planning library [44.144], and GraspIt!, a grasping simulator [44.145].

Another exciting trend is in open-source hardware, where CAD models and the technical details of construction of devices are made freely available [44.147, 148]. The Arduino project [44.149] is a widely used open-source microcontroller platform, and has been used in many robotics projects. The Raven [44.150] is an open-source laparoscopic surgery robot developed as a research platform an order of magnitude less expensive than commercial surgical robots [44.151].

The Cloud can also be used to facilitate open challenges and design competitions. For example, the African Robotics Network with support from IEEE Robotics and Automation Society hosted the \$10 Robot Design Challenge in the summer of 2012. This open competition attracted 28 designs from around the world including a winning entry from Thailand (Fig. 44.16) that modified a surplus Sony game controller, adapting its embedded vibration motors to drive wheels and adding lollipops to the thumb switches as inertial counterweights for contact sensing, which can be built from surplus parts for US \$8.96 [44.140].

44.5.5 Crowdsourcing and Call Centers

In contrast to automated telephone reservation and technical support systems, consider a future scenario where errors and exceptions are detected by robots and automation systems, which then access human guidance on-demand at remote call centers. Human skill, experience, and intuition is being tapped to solve a number of problems such as image labeling for computer vision [44.54, 62, 102, 152]. Amazon's Mechanical Turk is pioneering on-demand *crowdsourcing* that can draw on *human computation* or *social computing systems*. Research projects are exploring how

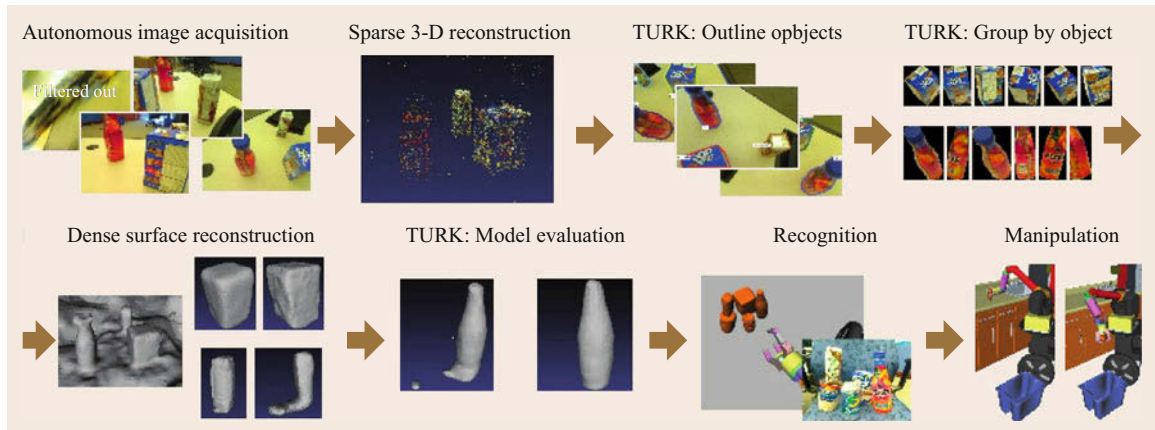

Fig. 44.17 A cloud robot system that incorporates Amazon's Mechanical Turk to *crowdsource* object identification to facilitate robot grasping (after [44.146])

this can be used for path planning [44.153], to determine depth layers, image normals, and symmetry from images [44.154], and to refine image segmenta-

tion [44.155]. Researchers are working to understand pricing models [44.156] and apply crowdsourcing to grasping [44.146] (Fig. 44.17).

44.6 Conclusion and Future Directions

As this technology matures, networked robots will gradually go beyond university laboratories and find application in the real world.

As mentioned earlier in Sects. 44.2.2 and 44.5, the new efforts in cloud robotics lead by Google and RoboEarth naturally bridge research and applications. The open source nature and ready-to-use APIs can quickly spread and deploy research results. Japan's Advanced Telecommunications Research Institute International (ATR) Intelligent Robotics and Communication Laboratory has also announced its networked robot project led by Norihiro Hagita (ATR). Its mission is to develop network-based intelligent robots for applications such as service, medical, and safety. Hideyuki Tokuda (Keio University) chaired the Networked Robot Forum in Spring 2005, which promotes research and development (R&D) and standardization on network robots through activities to support awareness campaigns and verification experiments in collaboration among wide-ranging parties, which includes over 100 industry and academic members. Korea's Ministry of Information and Communication has also announced the Ubiquitous Robotic Companion (URC) project to develop network-based intelligent robots.

Networked robots have allowed tens of thousands of nonspecialists around the world to interact with robots. The design of networked robots presents a number of engineering challenges to build reliable systems that can be operated by nonspecialists 24 h a day, 7 days a week, and remain online for years. Many new research challenges remain:

- *New interfaces:* As portable devices such as cell-phones and tablet computers increase in computation power, networked robotics should be able to adopt them as new interfaces. As computers become increasingly powerful, they become capable of visualizing more sophisticated sensor inputs. Designers of new interfaces should also keep track of new developments in hardware such as haptic interfaces and voice recognition systems. New software standards such as flash, extensible markup language (XML), extensible hyper text markup language (XHTML), virtual reality modeling language

(VRML), and wireless markup language (WML) will also change the way we design interface.

New interface technology arises as human computer interaction technology, mobile computing, and computer graphics areas progress. Recent progresses on brain-machine interaction explore the possibility of using brain wave, such as electroencephalography (EEG) signals, to control robot movements for ground robots [44.157] and unmanned aerial vehicles (UAV)s [44.158]. Gesture [44.159] and multitouch [44.160] are also used to generate control commands. Unlike the traditional mouse and keyboard interfaces, the new interfaces facilitate more natural interaction but suffers from precision issues, because these methods have large noise and require more research efforts in improving robustness and accuracy.

- *New algorithms:* Algorithms determine performance. Scalable algorithms that are capable of handling large amounts of data such as video/sensor network inputs and utilize fast-evolving hardware capability such as distributed and parallel computation will become increasingly important in the networked robotics, especially in cloud robotics.
- *New protocols:* Although we have listed some pioneering work in changing the network environment to improve teleoperation, there are still a large number of open problems such as new protocols, appropriate bandwidth allocation [44.161], QoS [44.162], security, routing mechanisms [44.29, 163], and many more. Network communication is a very fast-evolving field. The incorporation/modification of network communication ideas into networked telerobotic system design will continue to be an active research area. The common object request broker architecture (CORBA) or real-time CORBA [44.20, 21, 39, 164, 165] have great potential for networked robots.
- *New performance metrics:* As more and more robots enter service, it is important to develop metrics to quantify the performance of the robot-human team. As we are more familiar with metrics developed to assess robot performance or task performance [44.162], recent progresses on using the robot to assess human performance [44.166,

167] shed light on new metrics. Standardizing these metrics will also be an important direction.

- *Video for robotics*: Another interesting observation is that all of existing video compression and transmission standards try to rebuild a true and complete representation of camera field of view. However, it might not be necessary or infeasible due to bandwidth limit for a networked robot [44.168]. Sometimes, a high level abstraction is sufficient. For example, when a mobile robot is avoiding a moving obstacle, all the robot needs to know is the speed and bounding box of the moving object instead of knowledge that whether this object is human or other robots. We might want to

control the level of details in video perception and transmission. This actually imposes an interesting problem: we need a new streaming standard that serves for networked robots.

- *Applications*: Recent successful applications include environment monitoring [44.43, 169], manufacturing [44.170, 171], and infrastructure inspection and maintenance [44.172, 173]. The fast development of networked robot systems is worldwide. Many new applications are emerging in areas such as security, inspection, education, and entertainment. Application requirements such as reliability, security, and modularity will continue to pose new challenges for system design.

Until the mid 1960s, robots were only able to move in a predetermined workspace, the one they could reach from their firmly fixed base. **Part E** is about their conquest of the whole space. Mobile Robotics started as a research domain in its own right in the late 1960s with the Shakey project at SRI. 2015 marks the 50th anniversary of this seminal project that had a lasting legacy such as *A**. The seminal paper by N.J. Nilsson *A Mobile Automaton: An Application of Artificial Intelligence Techniques* at the International Joint Conference on Artificial Intelligence (IJCAI) 1969, already addressed perception, mapping, motion planning, and the notion of control architecture. Those issues would indeed be at the core of mobile robotics research for the following decades. The 1980s boomed with mobile robot projects, and as soon as it was necessary to cope with the reality of the real physical world, problems appeared that fostered novel research directions, actually moving away from the original concept in which the robot was just an application of artificial intelligence (AI) techniques. This part addresses all the issues that, put together, are necessary to build and control a mobile robot, except for the mechanical design itself.

Navigation is the capacity of moving from one location to another arbitrarily distant one. To move efficiently, a robot needs to use appropriate representations of its environment in order to plan and control its motions according to the presence of obstacles and terrain difficulties, and also to use environment features as landmarks for its localization. This is the topic of **Chapter 45** which addresses the different representations used for indoors or outdoors environments, including topological maps and semantic attributes.

However, building environment maps is usually achieved incrementally, as the robot discovers its environment while navigating in it. Hence partial perceptions built from different positions, need to be fused together – taking into account sensing errors and uncertainties (see **Chapter 5**, Part A) to construct a consistent global map. This requires the robot to know these positions, and, because of motion inaccuracies,

the transforms between them are uncertain. This requires to reference the positions to environment features which are only defined in the environment map itself. As a result, localization needs the map and mapping needs localization. Hence, localization and mapping are two interwound problems that must be solved simultaneously. The solution to this problem is the topic of **Chapter 46**.

Once environment maps are available, or during their construction, the robot has to plan its path as optimally as possible to reach its targets while avoiding obstacles. **Chapter 7** in Part A overviews the techniques for solving this central problem, which requires geometrical reasoning in the configuration space (CS) whose construction is complex. To avoid an explicit construction of the CS, probabilistic techniques proved the most efficient way to compute paths – at the price of optimality. However, the kinematic constraints of the robot's locomotion system such as non-holonomy have to be taken into account. We see in **Chapter 47** in this part how control problems cannot be separated from geometry. This chapter addresses motion planning from the viewpoint of mobile robotics and introduces the tools from control theory and differential geometry that enable to tackle kinematics constraints. In addition, it provides an overview of local sensor-based methods that are used when the robot encounters unknown or mobile obstacles while moving.

The rest of this part essentially focusses on various means of locomotion used to move in the environment: legged locomotion (**Chapter 48**), robots with wheels (**Chapter 49**), with tracks (**Chapter 50**), and underwater and aerial robots (**Chapters 51** and **52** respectively) which face the specific problems of three-dimensional (3-D) motion with environment perturbations. In these two last cases the close links between Robotics and Control are of course central.

Finally, after explaining how one single robot moves in different environments, Part E concludes with **Chapter 53** on the interaction and coordination of multiple mobile robot systems.

45. World Modeling

Wolfram Burgard, Martial Hebert, Maren Bennewitz

In this chapter we describe popular ways to represent the environment of a mobile robot. For indoor environments, which are often stored using two-dimensional representations, we discuss occupancy grids, line maps, topological maps, and landmark-based representations. Each of these techniques has its own advantages and disadvantages. Whilst occupancy grid maps allow for quick access and can efficiently be updated, line maps are more compact. Also landmark-based maps can efficiently be updated and maintained, however, they do not readily support navigation tasks such as path planning like topological representations do.

Additionally, we discuss approaches suited for outdoor terrain modeling. In outdoor environments, the flat-surface assumption underling many mapping techniques for indoor environments is no longer valid. A very popular approach in this context are elevation and variants maps, which store the surface of the terrain over a regularly spaced grid. Alternatives to such maps are point clouds, meshes, or three-dimensional grids,

which provide a greater flexibility but have higher storage demands.

The construction of models of the environment is crucial to the development of several applications of mobile robot systems. It is through these environment models that the robot can adapt its decisions to the current state of the world. The models are constructed from sensor data as the robot discovers its environment. There are three challenges in constructing environment models from sensor data. First, the models must be compact so that they can be used efficiently by other components of the system, such as path planners. Second, the models must be adapted to the task and to the type of environment. For example, modeling the environment

as a set of planes is not relevant to a robot operating in natural terrain. In particular, this implies that a *universal* representation for mobile robots is not possible and that we must instead choose from an array of different approaches. Third, the representation must accommodate the uncertainty inherent to both sensor data and to the robot's state estimation system. The latter point is particularly important since environment models typically accumulate sensor readings over substantial distances into a common reference frame. Drift in position estimates are unavoidable and must be accounted for in the model representation and in its construction.

45.1 Historical Overview

Historically, work in this area concentrated first on robots operating in indoor environments. In that case, the models take advantage of the fact that the world can be represented as vertical structures on reference ground planes. This simplification can be used for representing the world as a two-dimensional (2-D) grid. Uncertainty in the measurements and in the robot's pose can then be modeled by using probabilities of occupancy in the grid rather than binary occupied/empty flags. Another feature of indoor environments is that they are highly structured in that they contain primarily linear structures such as lines and planes. This observations led to a second class of representations based on collections of points, lines, and planes to represent the environment. Here again, a lot of attention was paid to representing the uncertainty on the relative poses of these geometric elements, including a considerable amount of work in the 1980s on using Kalman filters and other probabilistic techniques.

With continued progress on sensing (e.g., three-dimensional laser range scanners and stereo vision), and on mechanical and controls aspects of mobile robots systems, it became possible to develop mobile robot systems for operations in unstructured, natural terrain, motivated in part by planetary exploration and military applications. In these scenarios, it is no longer appropriate to project the data in a 2-D grid, and environments cannot be described adequately by a small vocabulary of geometric elements. Since, in most cases, it is still appropriate to assume (at least locally) that there is a reference ground plane, a natural representation is a two-and-a-half-dimensional 2.5-D grid, in which each cell contains the elevation (and possibly other features) of the terrain at that location. Although they have been used extensively, the main challenges with such *elevation maps* are that they are not compact representations and that it is difficult to incorporate uncertainty in the representation. Accordingly, much of the research has focused on designing efficient data structures and algorithms for elevation maps, for example, hierarchical representations. Recently, the uncertainty challenge has been tackled by using probabilistic variants of elevation maps.

While elevation maps provide a natural representation for many types of natural terrains, they cannot represent environments with vertical or overhanging structures. This limitation has become more evident in

recent years as applications of mobile robots are increasingly demanding operation in urban environment (in which building walls and other structures cannot be represented by elevation maps) and the use of aerial data, which involves overhanging structures such as tree canopies. This has led to the development of representations that are truly three-dimensional (3-D), such as point clouds, 3-D grids, and meshes. The two challenges described above apply here as well, except that the situation is more complicated because of the increased complexity introduced by the third dimension. Current research includes efficient computation over 3-D structures and probabilistic representations of 3-D data.

Because of the large volume of data involved in all of these representations, it is important to be able to group the data into larger chunks corresponding to semantically meaningful parts of the environment. This can be done at different levels, depending on the application the environment. At the lowest level, work in this area involves classifying the points into classes that are relevant to navigation tasks (e.g., distinguishing between vegetation and ground, extracting walls, tree surfaces, etc.). At an intermediate level of representation, this part of the work involves extracting parts of the environments that are considered landmarks of interest for the navigation task (e.g., roads). Finally, the highest representation level involves extracting and representing objects in the environments (e.g., natural obstacles, or specific objects such as cars for operation in urban environments).

All of these representations assume a static environment. In fact, many of the current applications of mobile robots call for operation in mixed environments in which the robot shares its environments with other moving agents, including other robots, people, and vehicles. Assuming that perception algorithms are able to detect and track individual moving objects in the environment, the challenge here is to insert this information into a representation that can be used by a planner. In this case, any one of the previous representations can be used as a foundation, but it needs to be extended to handle the temporal dimension by storing a history of the locations and states of the detected objects. Such representations include the trajectories of the detected objects and, in some cases, information on the future predicted trajectories of the objects.

45.2 Models for Indoors and Structured Environments

45.2.1 Occupancy Grids

Occupancy grid maps, which were introduced in the 1980s by *Moravec* and *Elfes* [45.1], are a popular, probabilistic approach to represent the environment. They are an approximative technique in which we calculate for each cell of a discrete grid the posterior probability that the corresponding area in the environment is occupied by an obstacle. The advantage of occupancy grid maps lies in the fact that they do not rely on any predefined features. Additionally, they offer a constant-time access to grid cells and provide the ability to represent unknown (unobserved) areas, which can be important, for example, in exploration tasks. Their disadvantage lies in potential discretization errors and the high memory requirements.

Throughout this section we assume that the map m consists of a discrete, two-dimensional grid of L cells denoted as m_1, \dots, m_L . Given the sensory input $z_{1:t}$ obtained by the robot at the corresponding positions $x_{1:t}$, the occupancy grid mapping approach calculates a posterior probability $p(m | x_{1:t}, z_{1:t})$.

To keep the calculations tractable, the overall approach assumes that the individual cells of the grid are independent, i.e., that the following equation holds

$$p(m | x_{1:t}, z_{1:t}) = \prod_{l=1}^L p(m_l | x_{1:t}, z_{1:t}) . \quad (45.1)$$

Note that this assumption is rather strong. It basically states that any information about the occupancy of one cell does not tell us anything about its neighboring cells. In practice, we often find objects that are larger than the individual grid cells, like doors, cabinets, chairs etc. Thus, if we know that one cell is occupied, for each of its neighboring cells the probability raises that it is occupied. Despite this fact, occupancy grid maps have been successfully applied in numerous installations of mobile robots and have been proven to be a powerful tool that supports various navigation tasks such as localization and path planning.

Because of the independence assumption expressed by (45.1) we can concentrate on the estimation of the occupancy probability of the individual cells m_l in m . Under additional independence assumptions one can finally arrive at the following formula for calculating the occupancy probability $p(m_l | x_{1:t}, z_{1:t})$ that cell m_l is occupied given the prior probability $p(m_l | x_{1:t-1}, z_{1:t-1})$ and the new observation z_t observed at position x_t

$$\begin{aligned} p(m_l | x_{1:t}, z_{1:t}) &= \left[1 + \frac{(1 - p(m_l | x_t, z_t))}{p(m_l | x_t, z_t)} \cdot \frac{p(m_l)}{(1 - p(m_l))} \right. \\ &\quad \left. \times \frac{1 - p(m_l | x_{1:t-1}, z_{1:t-1})}{p(m_l | x_{1:t-1}, z_{1:t-1})} \right]^{-1} . \end{aligned} \quad (45.2)$$

In practice, one often assumes that the prior $p(m_l)$ is 0.5 so that the second factor in the product becomes 1 and therefore vanishes from the equation.

Additionally, if we define

$$\text{Odds}(x) = \frac{p(x)}{1 - p(x)} , \quad (45.3)$$

the incremental updates can be computed using the following equation

$$\begin{aligned} \text{Odds}(m_l | x_{1:t}, z_{1:t}) &= \text{Odds}(m_l | x_t, z_t) \cdot \text{Odds}(m_l)^{-1} \\ &\quad \times \text{Odds}(m_l | x_{1:t-1}, z_{1:t-1}) . \end{aligned} \quad (45.4)$$

To recover the occupancy probability from the Odds representation given in (45.4), one can use the following formula, which can easily be derived using (45.3)

$$p(x) = \frac{\text{Odds}(x)}{1 + \text{Odds}(x)} . \quad (45.5)$$

It remains to describe how to compute the occupancy probability $p(m_l | x_t, z_t)$ of a grid cell given a *single* observation z_t and the corresponding pose x_t of the robot. This quantity strongly depends on the sensor of the robot and has to be defined individually for each type of sensor. Additionally, the parameters of these models have to be adapted according to the properties of each sensor. Let us assume that the function $\text{dist}(x_t, m_l)$ refers to the distance between the sensor at pose x_t and the center of the cell m_l . Let us first assume that we only need to consider the optical axis of the sensor cone as is, for example, the case for laser beams sent out by a laser range finder. Then, $p(m_l | x_t, z_t)$ can be formulated as

$$p(m_l | x_t, z_t) = \begin{cases} p_{\text{prior}}, & z_t \text{ is a maximum range reading} \\ p_{\text{prior}}, & m_l \text{ is not covered by } z_t , \\ p_{\text{occ}}, & |z_t - \text{dist}(x_t, m_l)| < r/2 \\ p_{\text{free}}, & z_t \geq \text{dist}(x_t, m_l) \end{cases} , \quad (45.6)$$

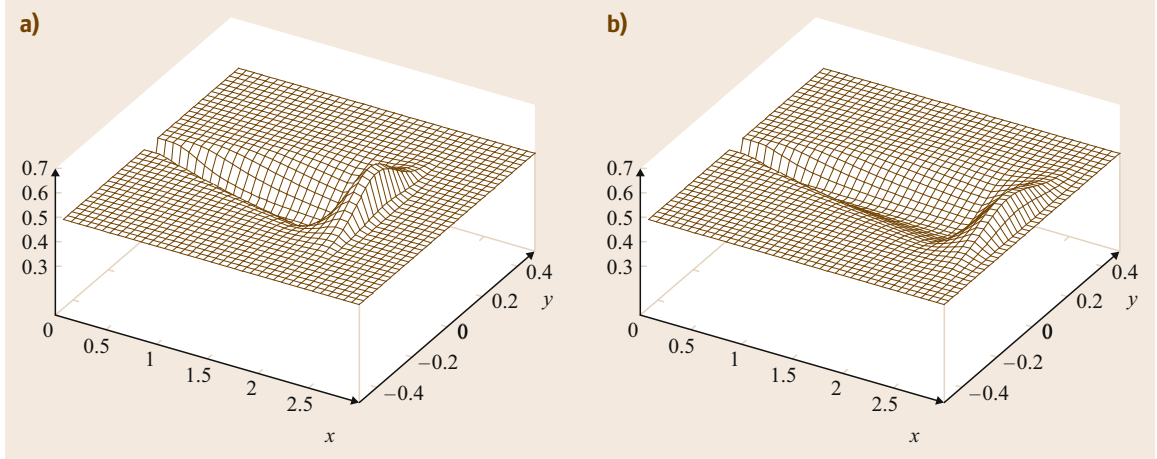

Fig.45.1a,b Occupancy probability introduced by a single ultrasound measurement of (a) $z = 2.0$ m and (b) $z = 2.5$ m (after [45.2])

where r is the resolution of the grid map. Obviously, it must hold $0 \leq p_{\text{free}} < p_{\text{prior}} < p_{\text{occ}} \leq 1$.

If a sonar sensor is used, the sensor model is slightly more complicated, since the sensor is not a beam sensor and the observations are more noisy than the ones of a laser range finder. To deal with these properties, one can use a mixture of three functions to express the model. First, the influence of an observation (which is represented by the difference between p_{prior} and p_{occ} as well as between p_{prior} and p_{free}) decreases with the measured distance. Second, the proximity information of a sonar is substantially affected by noise. This can be considered by employing a piecewise linear function to model a smooth transition from p_{free} to p_{occ} . Finally, the sonar sensor should not be modeled as a beam sensor, since it sends out a conic signal. The accuracy of an observation decreases with the angular distance between the cell under consideration and the optical axis of the observation. This is expressed by the derivation from the prior and is typically modeled using a Gaussian with zero mean. Therefore, it is maximal along the optical axis and decreases the bigger the angular distance from the optical axis is [45.2].

Two examples of resulting models are depicted in Fig. 45.1, which shows two three-dimensional plots of the resulting occupancy probabilities for a measurement of 2 m (Fig. 45.1a) and 2.5 m (Fig. 45.1b). In this figure, the optical axis of the sensor cone was identical with the x -axis and the sensor was placed in the origin of the coordinate frame. As can be seen, the occupancy probability is high for cells whose distance to x_t is close to z_t . It decreases for cells with shorter distance than z_t as well as with increasing values of the angular distance.

Figure 45.2 depicts the mapping process for a sequence of observations recorded with an iRobot B21r

robot. The first row shows how a map was built from a sequence of previous ultrasound scans. Afterwards the robot perceived a series of 18 ultrasound scans, each consisting of 24 measurements. The occupancy probabilities for these 18 scans are depicted in rows 2–7. The occupancy probability grid obtained by integrating the individual observations into the map is shown in the last row of this figure. As can be seen, the belief converges to a representation of the corridor structure in which the scans were recorded. A typical resulting map obtained for an indoor environment is depicted in Fig. 45.3.

45.2.2 Line Maps

The representation of the environment by line models is a popular alternative to the grid-based approximations described above. Line models have several advantages over these nonparametric representations. They require substantially less memory than grids and therefore scale better with the size of the environment. They furthermore are more accurate since they do not suffer from discretization problems. In this section, we consider the problem of calculating lines that provide the approximation of a set of range points by a line. If the data points are given by n pairs (x_i, y_i) of Cartesian coordinates, the line that minimizes the squared distances to all points can be calculated in closed form according to

$$\tan 2\phi = \frac{-2 \sum_i (\bar{x} - x_i)(\bar{y} - y_i)}{\sum_i [(\bar{y} - y_i)^2 - (\bar{x} - x_i)^2]}, \quad (45.7)$$

$$r = \bar{x} \cos \phi + \bar{y} \sin \phi, \quad (45.8)$$

where $\bar{x} = \frac{1}{n} \sum_i x_i$ and $\bar{y} = \frac{1}{n} \sum_i y_i$. In these equations, r is the normal distance of the line from the origin and ϕ is angle of the normal.

Unfortunately, there is no closed-form solution for situations in which the data points are generated by multiple linear structures. In such a situation two problems arise. First one has to answer the question how many lines there are, and second one has to solve a data association problem, which is to find the assignment of the data points to the individual lines. Once the number of lines and the associations are known, we can apply (45.7) and (45.8) to calculate the individual line parameters.

There is a popular approach to solve this problem for range scans with multiple linear structures. This approach, which goes back to the work of *Douglas and Peucker* [45.3], is also known as the *split-and-merge* algorithm. Its key idea is to recursively subdivide the point set into subsets that can be more accurately approximated by a line. The approach starts with the line calculated from all data points and determines the data point with maximum distance from this line. If this distance is below a given threshold, the algorithm terminates and provides the fitted line as output. Otherwise, it calculates the point with the largest distance from the line that connects the first and the last point. This point is the so-called splitting point. It then divides the point set into two subsets, one containing all points from the first up to the splitting point and one containing all points after the splitting point. The algorithm is then recursively applied to the two subsets. Figure 45.4 shows a visualization of the procedure.

Whereas the split-and-merge algorithm is quite effective and efficient, it is not guaranteed that the resulting model is actually optimal, i.e., is the model that minimizes the squared distances of all data points. One approach that is able to find such a model is based on the expectation maximization (EM) algorithm, which in the application described here can be regarded as a variant of the fuzzy *k*-means clustering algorithm. Let us suppose that the number m of lines in the model θ is known. Let us furthermore suppose that the likelihood of a data point $z = (x, y)$ given the model θ consisting of the line set $\{\theta_1, \dots, \theta_m\}$ is defined as

$$p(z | \theta) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{1}{2} \frac{d(z, \theta_k)^2}{\sigma^2}\right), \quad (45.9)$$

where σ is the standard deviation of the measurement noise and θ_k is the line for which Euclidean distance $d(z, \theta_k)$ to z is minimal.

The goal of the EM algorithm is to generate an iterated sequence of models of increased likelihood. To achieve this, one introduces so-called correspondence variables $c_{ij} \in \{0, 1\}$ that specify to which linear component of the model each point belongs. Since the correct values of these assignment variables are unknown, one

Fig. 45.2 Incremental mapping in a corridor environment. The upper left image shows the initial map and the lower one shows the resulting map. The maps in between are the local maps built from the individual ultrasound scans perceived by the robot (after [45.2])

Fig. 45.3 Occupancy grid map obtained from ultrasound data (after [45.2])

estimates a posterior about their values. Let θ_j be a component of the model and z_i be a measurement. Then the expectation about c_{ij} , i.e., that measurement i belongs

Fig. 45.4 Split-and-merge algorithm applied to a point set

to line j is computed in the E-step as

$$E[c_{ij} | \theta_j, z_i] = p(c_{ij} | \theta_j, z_i), \quad (45.10)$$

$$= \alpha p(z_i | c_{ij}, \theta_j) p(c_{ij} | \theta_j), \quad (45.11)$$

$$= \alpha' p(z_i | \theta_j). \quad (45.12)$$

In the M-step, the algorithm then computes the parameters of the model by taking into account the expectations computed in the E-step

$$\theta_j^* = \arg \min_{\theta_j} \sum_i \sum_j E[c_{ij} | \theta_j, z_i] d^2(z_i, \theta_j'). \quad (45.13)$$

Given a fixed variance σ for all data points in z we can determine the most likely model in closed form according to the following equations, which are probabilistic variants of (45.7) and (45.8) that take into account the data association uncertainty given by the expectations calculated in the E-step

$$\tan 2\phi_j = \frac{-2 \sum_i E[c_{ij} | \theta_j, z_i] (\bar{x} - x_i)(\bar{y} - y_i)}{\sum_i E[c_{ij} | \theta_j, z_i] [(\bar{y} - y_i)^2 - (\bar{x} - x_i)^2]}, \quad (45.14)$$

$$r_j = \bar{x} \cos \phi_j + \bar{y} \sin \phi_j. \quad (45.15)$$

Here \bar{x} and \bar{y} are computed as

$$\bar{x} = \frac{\sum_i E[c_{ij} | \theta_j, z_i] x_i}{\sum_i E[c_{ij} | \theta_j, z_i]}, \quad \bar{y} = \frac{\sum_i E[c_{ij} | \theta_j, z_i] y_i}{\sum_i E[c_{ij} | \theta_j, z_i]}. \quad (45.16)$$

Figure 45.5 depicts a line map extracted from 311 823 data points using the EM-based approach. In this example, the model consists of 94 lines. One approach to

Fig. 45.5 Line map consisting of 94 lines generated for 311 823 range points generated with the EM-based approach (after [45.4])

determine the optimal number of lines is to utilize the Bayesian information criterion [45.4].

45.2.3 Topological Maps

In contrast to the previously discussed representations, which mainly focus on the geometric structure of the environment, topological representations have also received significant attraction. One of the pioneering approaches to topological mapping, which has been presented in 1988, is the work by Kuipers and Byun [45.7]. In this approach, the environment is represented by a graph-like structure, in which the nodes are locally distinguishable places and the nodes are travel edges along which the robot can move between the places (VIDEO 270). Here, distinctive places are identified according to the distance to nearby objects. The distinctive places were been defined by Choset and Nagatani [45.8] as the meet-points in the generalized Voronoi diagrams, i.e., the points with an out-degree of three or more. A generalized Voronoi diagram is the set of points equidistant from the closest two or more obstacle boundaries. Generalized Voronoi diagrams are a very popular representation as they can be considered as road-maps with a high correspondence to the topological structure of the environment. They

Fig. 45.6 Example of a generalized Voronoi graph (after [45.5])

Fig. 45.7 (a) Mobile robot mapping a set of stone rocks. The image (b) depicts the path and the estimated landmark positions. The manually determined positions of the rocks are marked by circles (after [45.6])

have been used extensively for path planning. To plan a path from a starting position to a goal point in the environment, all the robot has to do is to first plan a path to the generalized Voronoi graph, then along the generalized Voronoi graph, and then from the generalized Voronoi graph to the goal point [45.8]. Figure 45.6 shows an example generalized Voronoi graph for an indoor environment. Note that in this figure only those parts of the graph that can be traversed by the robot without colliding with objects are displayed.

45.2.4 Landmark-Based Maps

For environments with locally distinguishable features, landmark-based maps have been extensively used. If we assume that the position of the robot is always known, it simply remains to maintain an estimate about the positions of the individual landmarks over time. In a planar environment, m is represented by K two-dimensional Gaussians with mean μ_k and covariance Σ_k , one for

each landmark. If a linearized version of the perception problem is given, the individual Gaussians can be updated using the equations for the extended Kalman filter. Note that, compared to the use of the extended Kalman filter **EKF** for landmark-based simultaneous localization and mapping (**SLAM**), where we needed a $2K + 3$ -dimensional state vector (3 dimensions for the position of the robot and $2K$ dimensions for the positions of the individual landmarks), we only need K two-dimensional Gaussians to represent the entire map since the robot pose is known. This property, for example, has been utilized in the FastSLAM algorithm [45.6]. Over the last few years, the graph-based **SLAM** paradigm has become a popular approach for estimating landmark maps due to their ability of relinearizing the motion and the measurement functions (for more details see Chap. 46).

Figure 45.7a shows a robot equipped with a SICK laser range finder that maps the position of rocks. The right image depicts the path of the vehicle as well as the manually determined and automatically estimated landmark positions.

45.3 World and Terrain Models for Natural Environments

From a survey of environment modeling [45.9] with an emphasis on probabilistic techniques for indoor environments, a taxonomy can be created along several axis: metric versus topological versus semantic, robot-centric versus world-centric, or application-based. We choose to first review purely geometric models (elevation grid, 3-D grid, meshes), then geometric models with low-level attributes (cost maps), and then models with richer semantic attributes, to finish with heterogeneous and hierarchical models.

45.3.1 Elevation Grids

Assuming that the terrain can be represented as a function $h = f(x, y)$, where x and y are the coordinates of

a reference place and h is the corresponding elevation. A natural representation is a digital elevation map which stores the value of h at discrete locations (x_i, y_i) . Because they are simple data structures and can be generated from sensor data in a relatively straightforward manner, elevation maps have been used extensively for mobile robots operating in natural environments with no vertical surfaces or overhangs (e.g., for planetary exploration scenarios [45.10]). Several issues need to be addressed when using elevation maps for mobile robots.

A regularly sampled grid is appropriate when the sensor data is roughly uniformly distributed on the reference plane. This is the case, for example, with aerial data. For ground robots, however, the distribution of the data on the reference ground plane varies dramatically

Fig. 45.8 Example elevation map built by accumulating 3-D data from a range sensor

because of the small incidence angles with the reference plane. This can be addressed by using variable-size cells instead of regularly sampled cells. In that case, the distribution of the cells on the reference plane is designed to approximate the distribution of points that would be measured by the sensor on this reference plane. Such nonuniform representations are useful primarily in cases in which the map is referenced to the current position of the robot [45.11] (Fig. 45.9). Frequent resampling is needed if the map is expressed in a global reference frame.

Irrespective of the sampling scheme used to construct the reference grid, the density of data in the grid varies due to local self-occlusions of the terrain surface and to mismatches between the resolution of the projected sensor data and the resolution of the grid. This can be problematic because, from the point of view of a planner, the elevation map would appear as a scattering of cells with elevation data and cells with no evidence (Fig. 45.8). Various schemes have been proposed to remedy this problem. The basic idea is to estimate the elevation values of the empty cells by interpolating across the cells with known elevation values. This has to be done with great care to avoid filling up regions that correspond to parts of the environment

Fig. 45.9 Example of a robot-centric map with variable size (after [45.11])

occluded by the terrain (*range shadows*) in which elevation data should not be inferred. Such mistakes can be catastrophic since a planner may generate paths through areas that are entirely unknown. One general approach to this problem is to use surface interpolation techniques including a term that allows for discontinuities in the resulting surfaces [45.12]. An alternative approach is to use the visibility constraints induced by the known geometry of the sensor in order to estimate plausible values of elevation at each cell [45.13, 14].

A difficulty in interpolating techniques is to explicitly take into account the sensor uncertainty. In particular, it is difficult to account for the varying resolution of the sensor as a function of range in a fixed-resolution grid. An alternative is to use multiple grids at different resolutions. The appropriate resolution to be used at a particular point (x, y) can be decided based on the range from (x, y) to the closest sensor location to retrieve the value at (x, y) from the appropriate map for that resolution. Generally, coarser map resolutions are used for longer ranges. This approach eliminates the gaps in the map due to undersampling at long range from the sensor by using the optimal resolution based on sensor geometry [45.15].

Uncertainty in the sensor measurement is expressed most naturally with respect to the sensor frame, for example, by expressing the uncertainty in the direction of the measurement. As a result, converting such uncertainty models to elevation maps is difficult because a distribution in the direction of the measurement maps to a distribution in the reference plane, not a distribution on the elevation value at a particular grid point. When updating a cell based on sensory input, one has to take into account that the uncertainty in a measurement increases with the distance measured due to errors in the tilting angle. A popular approach to estimate the height h at location (x, y) is to use a Kalman filter. If we assume that σ is the standard deviation of the current measurement h in the vertical direction in (x, y) and σ_{t-1} is the standard deviation of the current estimate or h_{t-1} , we can apply the following equations to

Fig. 45.10 The standard deviation of a height measurements can be modeled to depend linearly on the distance of the grid cell to the sensor

Fig.45.11a–d Different versions of digital elevation maps (after [45.16]): (a) scan (point set) of a bridge, (b) a standard elevation map computed from this data set, (c) an extended elevation map, which correctly represents the underpass under the bridge, and (d) a multilevel surface map that correctly represents the height of the vertical objects

obtain the new estimate h_t with standard deviation σ_t ,

$$h_t = \frac{\sigma^2 h_{t-1} + \sigma_{t-1}^2 h}{\sigma_{t-1}^2 + \sigma^2}, \quad (45.17)$$

$$\sigma_t^2 = \frac{\sigma_{t-1}^2 \sigma^2}{\sigma_{t-1}^2 + \sigma^2}. \quad (45.18)$$

One possible solution to deal with varying uncertainties is to use a model in which the standard deviation of the height of a measurement increases linearly with the length of the range measurement, as indicated in Fig. 45.10.

Vegetation cover is another source of error in the recovery of terrain elevation by totally or partially occluding the ground surface from the vehicle sensors. Online learning techniques can address this issue by predicting ground elevation ahead of the vehicle based on past appearance observations of similar terrain and vehicle state over the terrain [45.17].

Intermediate representations between 2-D elevation maps and full 3-D representations, addressed below, are extended elevation maps [45.18] and so-called multilevel surface maps [45.16]. Such approaches are specifically useful in structured terrain with vertical objects or overhangs such as bridges (Fig. 45.11).

45.3.2 3-D Grids and Point Sets

Elevation maps as described above assume a reference direction. In many cases, that assumption is violated. An alternative is to represent the data directly in 3-D without projecting it on a reference 2-D plane. The advantage of doing this is that all the sensor data can be preserved in its original distribution and that there is no restriction on the geometry of the environment. Figure 45.12 shows an example representation using 3-D points. The drawbacks of SLAM systems operating on such point clouds [45.19–21] is that neither free space nor unknown areas can be modeled and that sensor noise and dynamic objects cannot be dealt with directly. Another problem is that very large sets of 3-D points are difficult to handle efficiently. The point cloud library [45.22] addresses this problem by providing an

octree-based implementation to store and address large point clouds in an efficient manner.

Data structures based on dynamic 3-D grids can also be used for this purpose [45.26]. An interesting characteristic of these representations is that they enable the computation of cost evaluated from the true local 3-D distribution of the data (as opposed to costs

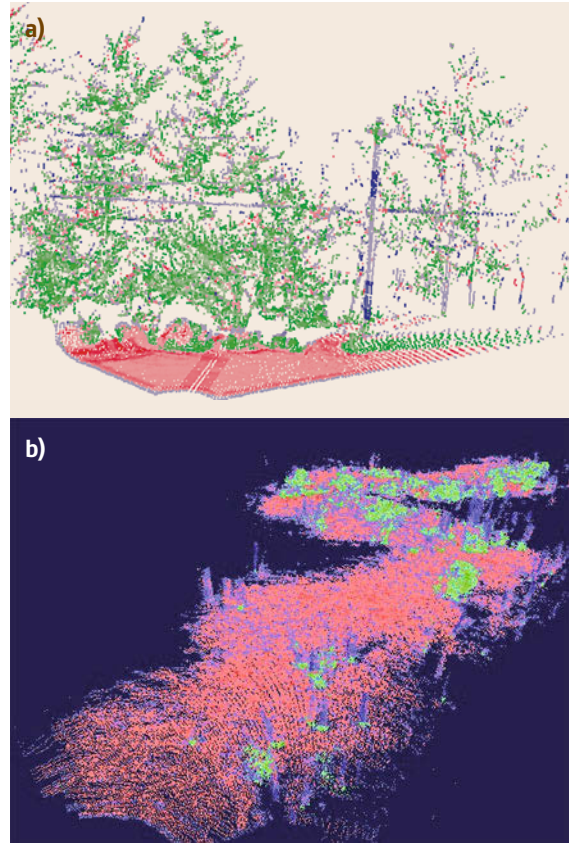

Fig.45.12a,b Example of mapping and classification of 3-D point sets: (a) 3-D data and classification result (green = vegetation, red = surfaces, blue = lines; the saturation of the color is proportional to the confidence in the classification result); (b) map accumulated over a large number of scans

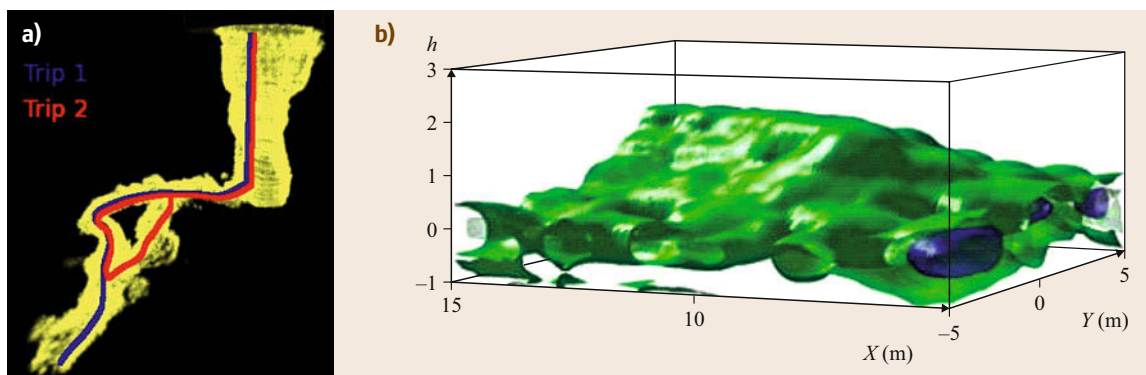

Fig. 45.13a,b Examples of volumetric maps for a natural environment. Whereas (a) shows a map of an underwater cave (after [45.23]), (b) depicts a terrain map obtained from a radar (after [45.24])

Fig. 45.14 Resulting octree-based representation of an outdoor environment at 0.2 m resolution (size of the scene: 292 m × 167 m × 28 m) (after [45.25]). For clarity, only occupied volumes are shown with height visualized by a color (gray scale) coding

computed from a local surface $z = f(x, y)$). This is important, for example, in environments with vegetation scatter, which cannot be modeled as a surface.

Extensions of occupancy grids to dense 3-D occupancy grids have been used successfully to model natural environments using a radar [45.24]. For more efficiently maintaining 3-D representations of even large-scale environments, also tree-based representations can be employed. In particular, octree-based 3-D representations have been employed, for example, to map an underwater cave from several sonars mounted on an underwater vehicle [45.23]. Example maps for these methods are presented in Fig. 45.13.

The OctoMap approach [45.27] uses octrees and supports a compact memory representation, multireso-

lution queries, and probabilistic occupancy estimates. The volumetric representation of space allows for explicitly representing free space and unknown areas. To exploit hierarchical dependencies in the environment it can be extended to maintain a collection of submaps in a tree-structure, where each node represents a subspace of the environment [45.28]. Figure. 45.14 and VIDEO 79 show an example outdoor map acquired from laser data and built by OctoMap. The OctoMap framework has been used successfully for various tasks including autonomous navigation with air vehicles [45.29], humanoid navigation in multilevel indoor environments [45.30], and mobile manipulation in cluttered environments [45.31, 32] where volumetric information is necessary to plan paths.

Fig.45.15a–c Two views (b–c) of the mesh representation of a map (a) obtained by scanning an environment. The meshes are reduced by a factor of 10 from the initial data

In the approaches mentioned above, the data sets are accumulated, sometimes probabilistically, into discrete environment volumes. A different approach is to represent the environment with discrete sensor samples integrated probabilistically into a metric map [45.33]. Such an approach is different from occupancy grids in several aspects: the storage requirement and resolution is adaptive instead of fixed and the potential for extensibility and scalability is higher.

45.3.3 Meshes

As described above, elevation maps are compact and easy to implement but they are restricted to a particular class of terrain; at the other extreme, using 3-D representations directly is more general but it is also more expensive computationally, and it does not represent explicitly surface continuity. A compromise is to represent the map by a mesh. This approach is attractive because it can, in principle, represent any combination of surfaces. It is also a compact representation in that, even though the size of the mesh may be initially very large, efficient mesh simplification algorithms exist in the literature [45.34] and can be used to reduce the map to a small number of vertices.

The key issue with meshes is that extraction of the correct surfaces from raw data can be difficult in complex environments. In practice, the data may be corrupted by sensor noise and by random clutter from other sources, such as vegetation, which cannot be represented as a continuous surface. In addition, it is necessary to precisely detect discontinuities in the data so that disconnected pieces of surface do not become accidentally linked in the mesh formation process [45.18]. Figure 45.15 shows typical mesh representations of an urban environment.

In some applications, the objective is to produce terrain models not to support autonomous navigation but to produce a model to be visualized to a human.

City planning is a typical application. Examples include producing 3-D texture models of urban environments using videos from a camera mounted on a moving vehicle equipped with an inertial navigation system [45.35] (VIDEO 269), using two laser scanners in push-broom mode, one for mapping and the other for localization [45.36], with a camera coregistered with the mapping laser, and collecting high-resolution laser data and imagery to produce geometric and photometric correct 3-D models of buildings [45.37]. Figure 45.16 depicts examples of textured meshes representing urban terrain.

45.3.4 Cost Maps

The most direct use of elevation maps is to compute traversability costs at each cell of the grid. The costs are computed by comparing the local terrain shape with a kinematic model of the robot. Several approaches have been proposed for computing the costs depending on the exact vehicle model; for example, a cost can be computed by considering the local slope and 3-D texture of the terrain [45.38]. More involved models take into account a detailed model of the robot dynamics. In that case, different costs are generated for different possible robot speeds and path curvatures. The cost grid is used in a minimum-cost planner (VIDEO 271). Since the terrain map is updated continuously as the robot traverses the environment, it is also necessary to update the costs continuously as new data arrives. Consequently, it is important that the planner is able to support changing costs without needing to process the entire grid every time new data is inserted.

An example of such a combination of grid representation and dynamic planner is the D* system, which uses a version of A* that fully supports dynamic grid updates [45.39–41]. Whenever a grid cell (or a group of grid cells) is updated, the planner makes minimal updates to its internal representation so that the optimal path can be updated quickly.

Fig. 45.16a–c Examples of urban terrain modeled as a textured mesh (a) (after [45.35]), (b) (after [45.37]), and (c) (after [45.36])

Defining the exact relation between the costs and the elevation values stored in the grid can be quite difficult. In fact, beyond the limiting cases of terrain with large elevation gradient or large slope, there is little guidance as to why a particular part of the terrain may be more traversable than another as it depends critically on the exact configuration of the robot. For this reason, recent work has focused on deriving cost maps directly from observations, rather than by using handcrafted algorithms. One approach involves learning the best weights to combine a set of predefined

costs. Another approach uses costs computed from other sources for inferring how to determine the costs on the terrain currently seen by the robot; for example, data from overhead imagery can be used to predict the traversability costs that should be used for a ground robot [45.42] (Fig. 45.17) or for learning to map local elevation distributions to costs values by analyzing actual robot trajectories through the terrain. Similar online learning approaches are used to predict terrain roughness [45.43], terrain slippage [45.44], or traversability in general [45.45, 46] to be used in a cost map.

Fig. 45.17 Example of online learning of cost (after [45.42]). The vehicle trajectory is represented in red. As the vehicle progresses, note the change in cost over all the map. The darker the appearance, the lower the cost

45.3.5 Semantic Attributes

The representations described above are concerned only with storing the data in a way that is compact and that can be used to estimate drivability costs. Often it is necessary to reason with high-level knowledge about the environment, e.g., the location and types of objects around the robot or the type of terrain (vegetation, mud, wall) in the environment. For convenience we will refer to this type of information as *semantic attributes* attached to different parts of the environment. There are several different ways to approach the problem of generating and representing semantic attributes. One possible direction is to approach the problem as

one of extracting *landmarks* from the environment. As for their indoor counterparts, outdoor environments can also be modeled using landmarks. Landmarks are defined broadly as scene elements easy to detect, salient in their surroundings, and easy to recognize. They can be specific objects, such as rocks [45.47], tree trunks in forest [45.48], or locations with a distinct appearance signature in 2-D or 3-D, for urban terrain [45.49, 50] or natural environments [45.51]. Landmarks can be used to produce topological representations of the environment or used in conjunction with metric maps. Recent efforts involve learning a compact representation of environments without defining a priori what a landmark should be [45.52, 53] or using statistical learning techniques [45.54] to extract new features from images. Nonlinear dimension-reduction techniques are used to obtain the representation and the results were demonstrated onboard ground and aerial vehicles (Fig. 45.18).

Another view of the problem is as a *classification and grouping* problem. Indeed, the map representations described in the earlier sections are low-level representations in that they do not attempt to group the data points into larger structures that are coherent with respect to geometry, terrain type, or semantic content. In practice, one would like to abstract the data into larger units that can be used by a planner or transmitted to another robot or an operator; for example, in an urban environment, one would like to group the parts of the data that belong to planes corresponding to pieces of walls. One such example is presented in Fig. 45.19.

One approach is to group 3-D points into components based on low-level classification and feature detection [45.58]. The shape of these component is analyzed further to discriminate between various natural object components (tree trunks, branches) and man-made obstacle (wires). Geometric primitives are then fitted to the components (mesh for the ground surface, ball tree for the vegetation, and cylinder to branches) to produce a compact high-level geometric description of the terrain.

Local terrain classification can be achieved by computing local features from the map and classifying each element of the map in different classes of terrain. This can be done from an elevation map, in which case the *elements* are the cells of the elevation map, or from a point cloud representation in which case the elements are 3-D locations. Given a location in the map x , a feature vector is $V(x)$ is computed in a neighborhood $N(x)$ of x and a classifier $f(V)$ returns the type of terrain at x . Features that have been used in the past are statistics of the distribution of the map data around each element, such as the slope and distribution of elevation [45.59], and the second-order moment of the distribution of the 3-D points in a neighborhood [45.58]. The ter-

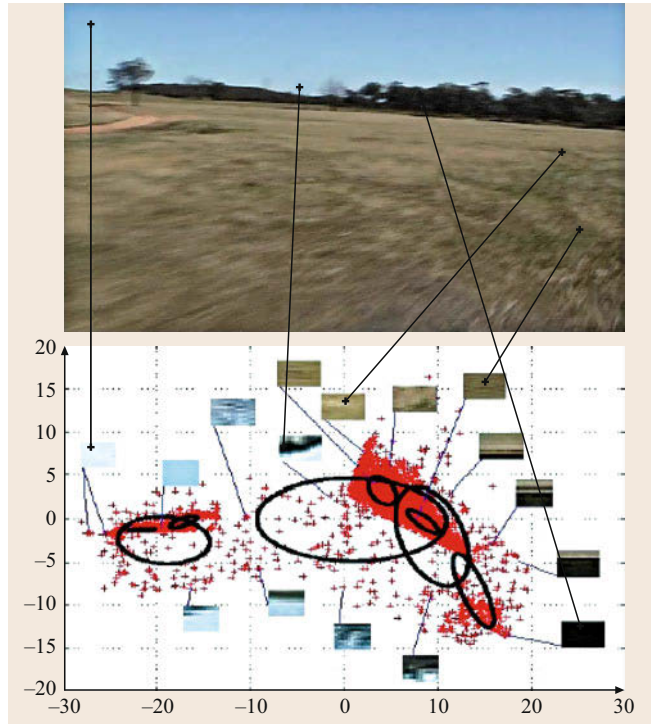

Fig. 45.18 Sample image and low-dimensional embedding of randomly sampled high-dimensional image patches (after [45.53])

Fig. 45.19 Terrain classification and extraction of geometric features. Whereas the 3-D data is shown on the left, the feature map with extracted planes and vegetation regions is shown on the right (after [45.55])

rain classes depend on the application. The most direct classification approach uses a binary classifier that separates the terrain into obstacle regions and traversable regions. More involved classifiers segment the map into more classes such as vegetation, solid surfaces, and linear structures [45.13, 58, 60]; an example is shown in Fig. 45.12. In some cases, it is possible to store, with each data element x in the map, the direction in which a measurement was taken for this element. In this case, it is possible to refine the classification by rea-

Fig. 45.20 (a) Structure learning for terrain classification (after [45.56]) and (b) building features extraction (after [45.57])

soning about the intersection of the measurement ray $d(x)$ with the rest of map; for example, this type of geometric reasoning [45.61] has been exploited to recover the load-bearing surface obscured by vegetation [45.51, 62, 63] and for extracting *negative* obstacles (such as ditches) [45.64]. In all of these cases, the classification information cannot be recovered directly from local statistics and must be inferred from longer-range geometric reasoning.

This class of approaches to local feature classification is similar to approaches for extracting features from images and it suffers from similar limitations. Specifically, these representations are sensitive to the choice of neighborhood used for computing the features. If it is too large, information over a large area is averaged out, leading to poor classification performance. If it is too small, there is not enough information in the neighborhood for reliable classification. The situation is complicated by the fact that the resolution of the map, or more precisely the density of data points in the map, may vary drastically as the distance from the sensor changes. This problem is addressed by using different neighborhood sizes at different locations in the map, or by tuning the classifier differently depending on the map location, typically based on distance from the sensor [45.15, 65]. A second problem is to generate the classifier f . This can be done by using a physical model that predicts the statistics of the local data distribution in the map assuming different terrain types [45.66]. This is generally difficult and a preferred approach is to train the classifier on training data.

This level of classification provides information about the local type of terrain, which can be used in planning, but it does not extract the extended geometric structures that may exist in the environment (Fig. 45.19). Geometric structures such as planar patches can in principle be extracted by using tech-

niques similar to the ones described in the context of indoor environments, such as EM, with the added difficulty that there is a larger amount of clutter that complicates the extraction of the patches. Robust techniques that can handle this level of clutter are typically used for extracting the planes [45.67, 68].

Classification based on local attributes can be improved significantly by taking into account contextual information; for example, hidden Markov models have been successfully used for laser data analysis to determine terrain traversability [45.69]. Another structure learning approach based on Markov random fields in conjunction with margin-maximization criterion has been demonstrated for a wide class of applications, including 3-D terrain classification and object segmentation [45.56] or building structures extraction [45.57] (Fig. 45.20). Finally there are approaches to detect, select, model, and recognize natural landmarks automatically for robot localization and environment mapping [45.47].

45.3.6 Heterogeneous and Hierarchical Models

For long-range navigation, an autonomous vehicle must perform numerous tasks, including absolute and relative localization, path planning, and reactive obstacle avoidance. In addition, it must perform some tasks to fulfill the mission requirements, detecting and modeling objects, for example. To achieve this, a hierarchical framework has been presented that accounts for the different scales and granularities of the representation needed [45.59]. Furthermore, models built from heterogeneous imagery sources (overhead, descent, and ground) have been used to produce 3-D multiresolution terrain models that support Mars exploration [45.70]. The hybrid metric map [45.71], enhances feature maps

Fig. 45.21 (a) A mobile robot acquiring a three-dimensional scan of an urban scene. (b) The people in the scene cause spurious data points in the resulting meshes. (c) The same scene after filtering people

with metric maps to provide a dense but compact environment representation. Another representation extracts

landmarks based on laser/imagery appearance as well as a metric map [45.72].

45.4 Dynamic Environments

The majority of techniques for mapping have been developed for static environments. Certain approaches like occupancy grids or elevation maps can in principle deal with dynamic environments in which objects move. Their drawback lies in the fact that the time to unlearn that a cell is free or that the elevation has changed can require as many observations as the robot received with the same area being occupied or with a different elevation. To resolve this problem, several alternative approaches have been proposed in the past. One very popular technique is to track moving objects using feature-based tracking algorithms [45.73, 74]. Such approaches are especially useful when the type of the dynamic objects is known in advance. They have been successfully applied in the context of learning three-dimensional city maps from range data. Figures 45.21 and 45.22 show applications in which dynamic objects were removed from the 3-D data acquired with mobile robots in urban scenes. Alternative approaches to such tracking techniques include those that learn maps on different time scales [45.75], that explicitly learn different states of

dynamic environments [45.76, 77], or that only map the static aspects [45.78].

Fig. 45.22 Complex three-dimensional scene acquired with a mobile robot after filtering dynamic objects (after [45.74])

45.5 Summary and Further Reading

Further reading about typical representations and how they can be utilized for mobile robot navigation can be found in recent textbooks on mobile robotics [45.2, 79,

80]. A comprehensive survey of the fundamentals of spatial data structures and their applications is available in *Samet* [45.81].

46. Simultaneous Localization and Mapping

Cyrril Stachniss, John J. Leonard, Sebastian Thrun

This chapter provides a comprehensive introduction in to the *simultaneous localization and mapping problem*, better known in its abbreviated form as **SLAM**. **SLAM** addresses the main perception problem of a robot navigating an unknown environment. While navigating the environment, the robot seeks to acquire a map thereof, and at the same time it wishes to localize itself using its map. The use of **SLAM** problems can be motivated in two different ways: one might be interested in detailed environment models, or one might seek to maintain an accurate sense of a mobile robot's location. **SLAM** serves both of these purposes.

We review the three major paradigms from which many published methods for **SLAM** are derived: (1) the extended Kalman filter (**EKF**); (2) particle filtering; and (3) graph optimization. We also review recent work in three-dimensional (**3-D**) **SLAM** using visual and red green blue dis-

tance-sensors (**RGB-D**), and close with a discussion of open research problems in robotic mapping.

This chapter provides a comprehensive introduction into one of the key enabling technologies of mobile robot navigation: *simultaneous localization and mapping*, or in short **SLAM**. **SLAM** addresses the problem of acquiring a spatial map of an environment while simultaneously localizing the robot relative to this model. The **SLAM** problem is generally regarded as one of the most important problems in the pursuit of building truly autonomous mobile robots. It is of great practical importance; if a robust, general-purpose solution to **SLAM** can be found, then many new applications of mobile robotics will become possible.

While the problem is deceptively easy to state, it presents many challenges, despite significant progress made in this area. At present, we have robust methods for mapping environments that are mainly static, struc-

tured, and of limited size. Robustly mapping unstructured, dynamic, and large-scale environments in an on-line fashion remains largely an open research problem.

The historical roots of methods that can be applied to address the **SLAM** problem can be traced back to Gauss [46.1], who is largely credited for inventing the least squares method. In the Twentieth Century, a number of fields outside robotics have studied the making of environment models from a moving sensor platform, most notably in *photogrammetry* [46.2–4] and *computer vision* [46.5]. Strongly related problems in these fields are bundle adjustment and structure from motion. **SLAM** builds on this work, often extending the basic paradigms into more scalable algorithms. Modern **SLAM** systems often view the estimation problem as solving a sparse graph of constraints and applying

nonlinear optimization to compute the map and the trajectory of the robot. As we strive to enable long-lived autonomous robots, an emerging challenge is to handle massive sensor data streams.

This chapter begins with a definition of the **SLAM** problem, which shall include a brief taxonomy of different versions of the problem. The centerpiece of this chapter is a layman introduction into the three major paradigms in this field, and the various extensions that exist. As the reader will quickly recognize, there is no single best solution to the **SLAM** method. The method

chosen by the practitioner will depend on a number of factors, such as the desired map resolution, the update time, and the nature of the features in the map, and so on. Nevertheless, the three methods discussed in this chapter cover the major paradigms in this field.

For more a detailed treatment of **SLAM**, we refer the reader to Durrant-Whyte and Bailey [46.6, 7], who provide an in-depth tutorial for **SLAM**, Grisetti et al. for a tutorial on graph-based **SLAM** [46.8], and Thrun et al., which dedicates a number of chapters to the topic of **SLAM** [46.9].

46.1 SLAM: Problem Definition

The **SLAM** problem is defined as follows: A mobile robot roams an unknown environment, starting at an initial location x_0 . Its motion is uncertain, making it gradually more difficult to determine its current pose in global coordinates. As it roams, the robot can sense its environment with a noisy sensor. The **SLAM** problem is the problem of building a map of the environment while simultaneously determining the robot's position relative to this map given noisy data.

46.1.1 Mathematical Basis

Formally, **SLAM** is best described in probabilistic terminology. Let us denote time by t , and the robot location by x_t . For mobile robots on a flat ground, x_t is usually a three-dimensional vector, comprising its two-dimensional (2-D) coordinate in the plane plus a single rotational value for its orientation. The sequence of locations, or *path*, is then given as

$$X_T = \{x_0, x_1, x_2, \dots, x_T\}. \quad (46.1)$$

Here T is some terminal time (T might be ∞). The initial location x_0 often serves as a point of reference for the estimation algorithm; other positions cannot be sensed.

Odometry provides relative information between two consecutive locations. Let u_t denote the odometry that characterized the motion between time $t-1$ and time t ; such data might be obtained from the robot's wheel encoders or from the controls given to those motors. Then the sequence

$$U_T = \{u_1, u_2, u_3, \dots, u_T\} \quad (46.2)$$

characterizes the relative motion of the robot. For noise-free motion, U_T would be sufficient to recover the poses from the initial location x_0 . However, odometry mea-

surements are noisy, and path integration techniques inevitably diverge from the truth.

Finally, the robot senses objects in the environment. Let m denote the *true* map of the environment. The environment may be comprised of landmarks, objects, surfaces, etc., and m describes their locations. The environment map m is often assumed to be time-invariant, i. e., static.

The robot measurements establish information between features in m and the robot location x_t . If we, without loss of generality, assume that the robot takes exactly one measurement at each point in time, the sequence of measurements is given as

$$Z_T = \{z_1, z_2, z_3, \dots, z_T\}. \quad (46.3)$$

Figure 46.1 illustrates the variables involved in the **SLAM** problem. It shows the sequence of locations and sensor measurements, and the causal relationships between these variables. This diagram represents a *graph*-

Fig. 46.1 Graphical model of the **SLAM** problem. Arcs indicate causal relationships, and shaded nodes are directly observable to the robot. In **SLAM**, the robot seeks to recover the unobservable variables

ical model for SLAM. It is useful in understanding the dependencies in the problem at hand.

The SLAM problem is now the problem of recovering a model of the world m and the sequence of robot locations X_T from the odometry and measurement data. The literature distinguishes two main forms of the SLAM problem, which are both of equal practical importance. One is known as the *full SLAM problem*: it involves estimating the posterior over the entire robot path together with the map

$$p(X_T, m \mid Z_T, U_T). \quad (46.4)$$

Written in this way, the full SLAM problem is the problem of calculating the joint posterior probability over X_T and m from the available data. Notice that the variables right of the conditioning bar are all directly observable to the robot, whereas those on the left are the ones that we want. As we shall see, algorithms for the full SLAM problem are often batch, that is, they process all data at the same time.

The second, equally important SLAM problem is the *online SLAM problem*. This problem is defined via

$$p(x_t, m \mid Z_t, U_t). \quad (46.5)$$

Online SLAM seeks to recover the present robot location, instead of the entire path. Algorithms that address the online problem are usually incremental and can process one data item at a time. In the literature, such algorithms are typically called *filters*.

To solve the SLAM problem, the robot needs to be endowed with two more models: a mathematical model that relates odometry measurements u_t to robot locations x_{t-1} and x_t ; and a model that relates measurements z_t to the environment m and the robot location x_t . These models correspond to the arcs in Fig. 46.1.

In SLAM, it is common to think of those mathematical models as probability distributions: $p(x_t \mid x_{t-1}, u_t)$ characterizes the probability distribution of the location x_t assuming that a robot started at a known location x_{t-1} and measured the odometry data u_t . And likewise, $p(z_t \mid x_t, m)$ is the probability for measuring z_t if this measurement is taken at a known location x_t in a known environment m . Of course, in the SLAM problem we do *not* know the robot location, and neither do we know the environment. As we shall see, Bayes rule takes care of this, by transforming these mathematical relationships into a form where we can *recover* probability distributions over those latent variables from the measured data.

46.1.2 Example: SLAM in Landmark Worlds

One common setting of SLAM involves an assumption that the environment is populated by point-landmarks.

When building 2-D maps, point-landmarks may correspond to door posts and corners of rooms, which, when projected into a 2-D map are characterized by a point coordinate. In a 2-D world, each point-landmark is characterized by two coordinate values. Hence the world is a vector of size $2N$, where N is the number of point-landmarks in the world. In a commonly studied setting, the robot can sense three things: the relative range to nearby landmarks, their relative bearing, and the identity of these landmarks. The range and bearing may be noisy, but in the most simple case the identity of the sensed landmarks is known perfectly. Determining the identity of the sensed landmarks is also known as the *data association problem*. In practice, it is one of the most difficult problems in SLAM.

To model the above described setup, one begins with defining the *exact*, noise-free measurement function. The measurement function h describes the workings of the sensors: it accepts as input a description of the environment m and a robot location x_t , and it computes the measurement

$$h(x_t, m). \quad (46.6)$$

Computing h is straightforward in our simplified landmark setting; it is a simple exercise in trigonometry. The probabilistic measurement model can be derived from this measurement function by adding a noise term. It is a probability distribution that peaks at the noise-free value $h(x_t, m)$ but allows for measurement noise, for example,

$$p(z_t \mid x_t, m) = \mathcal{N}(h(x_t, m), \mathbf{Q}_t). \quad (46.7)$$

Here \mathcal{N} denotes the 2-D normal distribution, which is centered at $h(x_t, m)$. The 2-by-2 matrix \mathbf{Q}_t is the noise covariance, indexed by time.

The motion model is derived from a kinematic model of robot motion. Given the location vector x_{t-1} and the motion u_t , textbook kinematics tells us how to calculate x_t . Let this function be denoted by g

$$g(x_{t-1}, u_t). \quad (46.8)$$

The motion model may then be defined by a normal distribution centered at $g(x_{t-1}, u_t)$ but subject to Gaussian noise

$$p(x_t \mid x_{t-1}, u_t) = \mathcal{N}(g(x_{t-1}, u_t), \mathbf{R}_t). \quad (46.9)$$

Here \mathbf{R}_t is a covariance. It is of size 3-by-3, since the location is a three-dimensional 3-D vector.

With these definitions, we have all we need to develop a SLAM algorithm. While in the literature,

point-landmark problems with range-bearing sensing are by far the most studied, **SLAM** algorithms are not confined to landmark worlds. But no matter what the map representation and the sensor modality, any **SLAM** algorithm needs a similarly crisp definition of the features in m , the measurement model $p(z_t | x_t, m)$, and the motion model $p(x_t | x_{t-1}, u_t)$. Note that none of those distributions has to be restricted to Gaussian noise as done in the example above.

46.1.3 Taxonomy of the **SLAM** Problem

SLAM problems are distinguished along a number of different dimensions. Most important research papers identify the type of problems addressed by making the underlying assumptions explicit. We already encountered one such distinction: full versus online. Other common distinctions are as follows:

Volumetric Versus Feature-Based

In volumetric **SLAM**, the map is sampled at a resolution high enough to allow for photo-realistic reconstruction of the environment. The map m in volumetric **SLAM** is usually quite high-dimensional, with the result that the computation can be quite involved. Feature-based **SLAM** extracts sparse features from the sensor stream. The map is then only comprised of features. Our point-landmark example is an instance of feature-based **SLAM**. Feature-based **SLAM** techniques tend to be more efficient, but their results may be inferior to volumetric **SLAM** due to the fact that the extraction of features discards information in the sensor measurements.

Topological Versus Metric

Some mapping techniques recover only a qualitative description of the environment, which characterizes the relation of basic locations. Such methods are known as topological. A topological map might be defined over a set of distinct places and a set of qualitative relations between these places (e.g., place A is adjacent to place B). Metric **SLAM** methods provide metric information between the relation of such places. In recent years, topological methods have fallen out of fashion, despite ample evidence that humans often use topological information for navigation.

Known Versus Unknown Correspondence

The correspondence problem is the problem of relating the identity of sensed things to other sensed things. In the landmark example above, we assumed that the identity of landmarks is known. Some **SLAM** algorithms make such an assumption, others do not. The ones that do not provide special mechanisms for estimating the correspondence of measured features to

previously observed landmarks in the map. The problem of estimating the correspondence is known as *data association problem*. It is one of the most difficult problems in **SLAM**.

Static Versus Dynamic

Static **SLAM** algorithms assume that the environment does not change over time. Dynamic methods allow for changes in the environment. The vast literature on **SLAM** assumes static environments. Dynamic effects are often treated just as measurement outliers. Methods that reason about motion in the environment are more involved, but they tend to be more robust in most applications.

Small Versus Large Uncertainty

SLAM problems are distinguished by the degree of location uncertainty that they can handle. The most simple **SLAM** algorithms allow only for small errors in the location estimate. They are good for situations in which a robot goes down a path that does not intersect itself, and then returns along the same path. In many environments it is possible to reach the same location from multiple directions. Here the robot may accrue a large amount of uncertainty. This problem is known as the *loop closing problem*. When closing a loop, the uncertainty may be large. The ability to close loops is a key characteristic of modern-day **SLAM** algorithms. The uncertainty can be reduced if the robot can sense information about its position in some absolute coordinate frame, e.g., through the use of a satellite-based global positioning system (**GPS**) receiver.

Active Versus Passive

In passive **SLAM** algorithms, some other entity controls the robot, and the **SLAM** algorithm is purely observing. The vast majority of algorithms are of this type; they give the robot designer the freedom to implement arbitrary motion controllers, and pursue arbitrary motion objectives. In active **SLAM**, the robot actively explores its environment in the pursuit of an accurate map. Active **SLAM** methods tend to yield more accurate maps in less time, but they constrain the robot motion. There exist hybrid techniques in which the **SLAM** algorithm controls only the pointing direction of the robot's sensors, but not the motion direction.

Single-Robot Versus Multi-Robot

Most **SLAM** problems are defined for a single robot platform, although recently the problem of multi-robot exploration has gained in popularity. Multi-robot **SLAM** problems come in many flavors. In some, robots get to observe each other, in others, robots are told their relative initial locations. Multirobot **SLAM** problems

are also distinguished by the type of communication allowed between the different robots. In some, the robots can communicate with no latency and infinite bandwidth. More realistic are setups in which only nearby robots can communicate, and the communication is subject to latency and bandwidth limitations.

Any-Time and Any-Space

Robots that do all computations onboard have limited resources in memory and computation power. Any-time and any-space SLAM systems are an alternative

to traditional methods. They enable the robot to compute a solution given the resource constraints of the system. The more resources available, the better the solution.

As this taxonomy suggests, there exists a flurry of SLAM algorithms. Most modern-day conferences dedicate multiple sessions to SLAM. This chapter focuses on the very basic SLAM setup. In particular it assumes a static environment with a single robot. Extensions are discussed towards the end of this chapter, in which the relevant literature is discussed.

46.2 The Three Main SLAM Paradigms

This section reviews three basic SLAM paradigms, from which most others are derived. The first, known as **EKF SLAM**, is in robotics historically the earliest but has become less popular due to its limiting computational properties and issues resulting from performing single linearizations only. The second approach uses nonparametric statistical filtering techniques known as particle filters. It is a popular method for online SLAM and provides a perspective on addressing the data association problem in SLAM. The third paradigm is based on graphical representations and successfully applies sparse nonlinear optimization methods to the SLAM problem. It is the main paradigm for solving the full SLAM problem and recently also incremental techniques are available.

46.2.1 Extended Kalman Filters

Historically, the **EKF** formulation of SLAM is the earliest, and perhaps the most influential, SLAM algorithm. **EKF SLAM** was introduced in [46.10, 11] and [46.12, 13], which were the first papers to propose the use of a single state vector to estimate the locations of the robot and a set of features in the environment, with an associated error covariance matrix representing the uncertainty in these estimates, including the correlations between the vehicle and feature state estimates. As the robot moves through its environment taking measurements, the system state vector and covariance matrix are updated using the extended Kalman filter [46.14, 15]. As new features are observed, new states are added to the system state vector; the size of the system covariance matrix grows quadratically.

This approach assumes a metrical, feature-based environmental representation, in which objects can be effectively represented as points in an appropriate parameter space. The position of the robot and the locations of features form a network of uncertain spatial relationships. The development of appropriate repre-

sentations is a critical issue in SLAM, and intimately related to the topics of sensing and world modeling discussed in Chap. 36 and in Part C.

The **EKF** algorithm represents the robot estimate by a multivariate Gaussian

$$p(x_t, m \mid Z_t, U_t) = \mathcal{N}(\mu_t, \Sigma_t). \quad (46.10)$$

The high-dimensional vector μ_t contains the robot's best estimate of its own current location x_t and the location of the features in the environment. In our point-landmark example, the dimension of μ_t would be $3 + 2N$, since we need three variables to represent the robot location and $2N$ variables for the N landmarks in the map.

The matrix Σ_t is the covariance of the robot's assessment of its expected error in the guess μ_t . The matrix Σ_t is of size $(3 + 2N) \times (3 + 2N)$ and it is positive semi-definite. In SLAM, this matrix is usually dense. The off-diagonal elements capture the correlations in the estimates of different variables. Nonzero correlations come along because the robot's location is uncertain, and as a result the locations of the landmarks in the maps are uncertain.

The **EKF SLAM** algorithm is easily derived for our point-landmark example. Suppose, for a moment, the motion function g and the measurement function h were *linear* in their arguments. Then, the vanilla Kalman filter, as described in any textbook on Kalman filtering, would be applicable. **EKF SLAM** linearizes the functions g and h using Taylor series expansion. In its most basic form and in the absence of any data association problems, **EKF SLAM** is basically the application of the **EKF** to the online SLAM problem.

Figure 46.2 illustrates the **EKF SLAM** algorithm for an artificial example. The robot navigates from a start pose that serves as the origin of its coordinate system. As it moves, its own pose uncertainty increases, as indicated by uncertainty ellipses of growing diameter. It

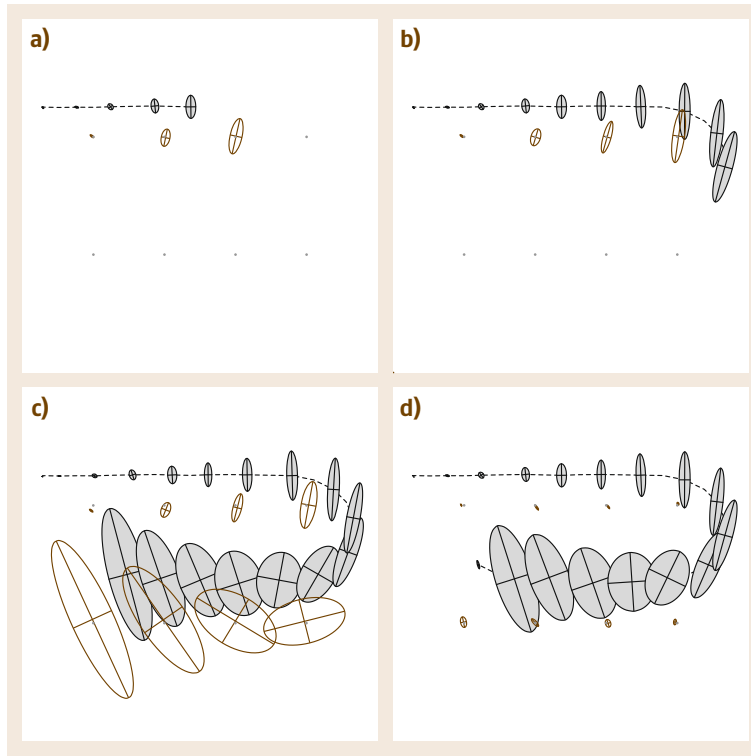

Fig. 46.2a–d EKF applied to the online SLAM problem. The robot's path is a *dotted line*, and its estimates of its own position are *shaded ellipses*. Eight distinguishable landmarks of unknown location are shown as *small dots*, and their location estimates are shown as *white ellipses*. In (a–c) the robot's positional uncertainty is increasing, as is its uncertainty about the landmarks it encounters. In (d) the robot senses the first landmark again, and the uncertainty of *all* landmarks decreases, as does the uncertainty of its current pose (image courtesy of Michael Montemerlo, Stanford University)

also senses nearby landmarks and maps them with an uncertainty that combines the fixed measurement uncertainty with the increasing pose uncertainty. As a result, the uncertainty in the landmark locations grows over time. The interesting transition happens in Fig. 46.2d: Here the robot observes the landmark it saw in the very beginning of mapping, and whose location is relatively well known. Through this observation, the robot's pose error is reduced, as indicated in Fig. 46.2d – notice the very small error ellipse for the final robot pose. This observation also reduces the uncertainty for other landmarks in the map. This phenomenon arises from a correlation that is expressed in the covariance matrix of the Gaussian posterior. Since most of the uncertainty in earlier landmark estimates is caused by the robot pose, and since this very uncertainty persists over time, the location estimates of those landmarks are correlated. When gaining information on the robot's pose, this information spreads to previously observed landmarks. This effect is probably the most important characteristic of the SLAM posterior [46.16]. Information that helps localize the robot is propagated through the map, and as a result improves the localization of other landmarks in the map.

With a few adaptations, **EKF SLAM** can also be applied in the presence of *uncertain data association*. If the identity of observed features is unknown, the basic

EKF idea becomes inapplicable. The solution here is to reason about the most likely data association when a landmark is observed. This is usually done based on proximity: *which of the landmarks in the map corresponds most likely to the landmark just observed?* The proximity calculation considers the measurement noise and the actual uncertainty in the poster estimate, and the metric used in this calculation is known as a Mahalanobis distance, which is a weighted quadratic distance. To minimize the chances of false data associations, many implementations use visible features to distinguish individual landmarks and associate groups of landmarks observed simultaneously [46.17, 18], although distinct features can also be computed from laser data [46.19, 20]. Typical implementations also maintain a *provisional landmark list* and only add landmarks to the internal map when they have been observed sufficiently frequently [46.16, 21]. With an appropriate landmark definition and careful implementation of the data association step, **EKF SLAM** has been applied successfully in a wide range of environments, using airborne, underwater, indoor, and various other platforms.

The basic formulation of **EKF SLAM** assumes that the location of features in the map is fully observable from a single position of the robot. The method has been extended to situations with partial observability,

with range-only [46.22] or angle-only [46.23, 24] measurements. The technique has also been utilized using a feature-less representation, in which the state consists of current and past robot poses, and measurements take the form of constraints between the poses (derived for example from laser scan matching or from camera measurements) [46.25, 26].

A key concern of the **EKF** approach to **SLAM** lies in the quadratic nature of the covariance matrix. A number of researchers have proposed extensions to the **EKF SLAM** algorithms that achieve scalability, for example through submap decomposition [46.27–30]. A related family of approaches [46.31–34] employs the Extended Information Filter, which operates on the inverse of the covariance matrix. A key insight is that whereas the **EKF** covariance is densely populated, the information matrix is sparse when the full robot trajectory is maintained, leading to the development of efficient algorithms and providing a conceptual link to the pose graph optimization methods described in Sect. 46.2.3.

The issues of consistency and convergence in **EKF SLAM** have been investigated in [46.35, 36]. Observability-based rules for designing consistent **EKF SLAM** estimators are presented in [46.37].

46.2.2 Particle Methods

The second principal **SLAM** paradigm is based on particle filters. Particle filters can be traced back to [46.38], but they have become popular only in the last two decades. Particle filters represent a posterior through a set of *particles*. For the novice in **SLAM**, each particle is best thought as a concrete guess as to what the true value of the state may be. By collecting many such guesses into a set of guesses, or set of particles, the particle filter approximates the posterior distribution. Under mild conditions, the particle filter has been shown to approach the true posterior as the particle set size goes to infinity. It is also a nonparametric representation that represents multimodal distributions with ease.

The key problem with the particle filter in the context of **SLAM** is that the space of maps and robot paths is huge. Suppose we have a map with 100 features. How many particles would it take to populate that space? In fact, particle filters scale exponentially with the dimension of the underlying state space. Three or four dimensions are thus acceptable, but 100 dimensions are generally not.

The trick to make particle filters amenable to the **SLAM** problem goes back to [46.39, 40] and is known as Rao–Blackwellization. It has been introduced into the **SLAM** literature in [46.41], followed by [46.42],

who coined the name **fastSLAM** (fast simultaneous localization and mapping). Let us first explain the basic FastSLAM algorithm on the simplified point-landmark example, and then discuss the justification for this approach.

At any point in time, FastSLAM maintains K particles of the type

$$X_t^{[k]}, \mu_{t,1}^{[k]}, \dots, \mu_{t,N}^{[k]}, \Sigma_{t,1}^{[k]}, \dots, \Sigma_{t,N}^{[k]}. \quad (46.11)$$

Here $[k]$ is the index of the sample. This expression states that a particle contains:

- A sample path $X_t^{[k]}$, and
- A set of N 2-D Gaussians with means $\mu_{t,n}^{[k]}$ and variances $\Sigma_{t,n}^{[k]}$, one for each landmark in the environment.

Here n is the index of the landmark (with $1 \leq n \leq N$). From that it follows that K particles possess K path samples. It also possesses KN Gaussians, each of which models exactly one landmark for one of the particles.

Initializing FastSLAM is simple: just set each particle's robot location to the starting coordinates, typically $(0, 0, 0)^T$, and zero the map. The particle update then proceeds as follows:

- When an odometry reading is received, new location variables are generated stochastically, one for each of the particles. The distribution for generating those location particles is based on the motion model

$$x_t^{[k]} \approx p(x_t | x_{t-1}^{[k]}, u_t). \quad (46.12)$$

Here $x_{t-1}^{[k]}$ is the previous location, which is part of the particle. This probabilistic sampling step is easily implemented for any robot whose kinematics can be computed.

- When a measurement z_t is received, two things happen: first, FastSLAM computes for each particle the probability of the new measurement z_t . Let the index of the sensed landmark be n . Then the desired probability is defined as follows

$$w_t^{[k]} = \mathcal{N}(z_t | x_t^{[k]}, \mu_{t,n}^{[k]}, \Sigma_{t,n}^{[k]}). \quad (46.13)$$

The factor $w_t^{[k]}$ is called the *importance weight*, since it measures how *important* the particle is in the light of the new sensor measurement. As before, \mathcal{N} denotes the normal distribution, but this time it is calculated for a specific value, z_t . The importance weights of all particles are then normalized so that they sum to 1.

Next, FastSLAM draws with replacement from the set of existing particles a set of new particles. The probability of drawing a particle is its normalized

importance weight. This step is called *resampling*. The intuition behind resampling is that particles for which the measurement is more plausible have a higher chance of surviving the resampling process.

Finally, FastSLAM updates for the new particle set the mean $\mu_{i,n}^{[k]}$ and covariance $\Sigma_{i,n}^{[k]}$, based on the measurement z_i . This update follows the standard EKF update rules – note that the extended Kalman filters maintained in FastSLAM are, in contrast to EKF SLAM, all low-dimensional (typically 2-D).

This all may sound complex, but FastSLAM is quite easy to implement. Sampling from the motion model usually involves simple kinematic calculations. Computing the importance of a measurement is often straightforward too, especially for Gaussian measurement noise. And updating a low-dimensional particle filter is also not complicated.

FastSLAM has been shown to approximate the full SLAM posterior. The derivation of FastSLAM exploits three techniques: Rao–Blackwellization, conditional independence, and resampling. Rao–Blackwellization is the following concept. Suppose we would like to compute a probability distribution $p(a, b)$, where a and b are arbitrary random variables. The vanilla particle filter would draw particles from the joint distributions, that is, each particle would have a value for a and one for b . However, if the conditional $p(b | a)$ can be described in closed form, it is equally legitimate to just draw particles from $p(a)$, and attach to each particle a closed-form description of $p(b | a)$. This trick is known as Rao–

Blackwellization, and it yields better results than sampling from the joint. FastSLAM applies this technique, in that it samples from the path posterior $p(X_i^{[k]} | U_i, Z_i)$ and represents the map $p(m | X_i^{[k]}, U_i, Z_i)$ in Gaussian form.

FastSLAM also breaks down the posterior over maps (conditioned on paths) into sequences of low-dimensional Gaussians. The justification for this decomposition is subtle. It arises from a specific conditional independence assumption that is native to SLAM. Fig. 46.3 illustrates the concept graphically. In SLAM, knowledge of the robot path renders all landmark estimates independent. This is easily shown for the graphical network in Fig. 46.3: we find that if we remove the path variables from Fig. 46.3, then the landmark variables are all disconnected [46.43]. Thus, in SLAM *any dependence between multiple landmark estimates is mediated through the robot path*. This subtle but important observation implies that even if we used a large, monolithic Gaussian for the entire map (one per particle, of course), the off-diagonal element between different landmarks would simply remain zero. It is therefore legitimate to implement the map more efficiently, using N small Gaussians, one for each landmark. This explains the efficient map representation in FastSLAM.

Figure 46.4 shows results for a point-feature problem; here the point features are the centers of tree trunks as observed by an outdoor robot. The dataset used here is known as the Victoria Park dataset [46.44]. Fig. 46.4a shows the path of the vehicle obtained by integrating the vehicle controls, without perception. As can be seen, controls are a poor predictor of location for this vehicle; after 30 min of driving, the estimated position of the vehicle is well over 100 m away from its GPS position.

The FastSLAM algorithm has a number of interesting properties. First, it solves both full and online SLAM problems. Each particle has a sample of an entire path but the actual update equation only uses the most recent pose. This makes FastSLAM a filter. Second, FastSLAM can maintain multiple data association hypotheses. It is straightforward to make data association decisions on a per-particle basis, instead of having to adopt the same hypothesis for the entire filter. While we will not give any mathematical justification, we note that the resulting FastSLAM algorithm can even deal with unknown data association – something that the extended Kalman filter cannot claim. And third, FastSLAM can be implemented very efficiently using advanced tree methods to represent the map estimates, the update can be performed in time logarithmic in the size of the map N , and linear in the number of particles M .

Fig. 46.3 The SLAM problem depicted as Bayes network graph. The robot moves from location x_{t-1} to location x_{t+2} , driven by a sequence of controls. At each location x_t it observes a nearby feature in the map $m = \{m_1, m_2, m_3\}$. This graphical network illustrates that the location variables *separate* the individual features in the map from each other. If the locations are known, there remains no other path involving variables whose value is not known, between any two features in the map. This lack of a path renders the posterior of any two features in the map conditionally independent (given the locations)

Fig. 46.4 (a) Vehicle path predicted by the odometry; (b) True path (*dashed line*) and FastSLAM 1.0 path (*solid line*); (c) Victoria Park results overlaid on aerial imagery with the GPS path in *blue (dashed)*, average FastSLAM 1.0 path in *yellow (solid)*, and estimated features as *yellow dots* (data and aerial image courtesy of José Guivant and Eduardo Nebot, Australian Centre for Field Robotics)

Fig. 46.5 Occupancy grid map generated from laser range data and based on pure odometry (image courtesy of Dirk Hähnel, University of Freiburg)

FastSLAM has been extended in several ways. One set of variants are grid-based versions of FastSLAM, in which the Gaussians used to model point landmarks are replaced by an occupancy grid map [46.45–47]. The variant of [46.46] is illustrated in Fig. 46.5.

Figure 46.6 illustrates a simplified situation with three particles just before closing a large loop. The three different particles each stand for different paths, and they also possess their own local maps. When the loop is closed importance resampling selects those particles

whose maps are most consistent with the measurement. A resulting large-scale map is shown in Fig. 46.5. Further extensions can be found in [46.48, 49], whose methods are called DP-SLAM and operate on ancestry trees to provide efficient tree update methods for grid-based maps. Related to that, approximations to FastSLAM in which particles share their maps have been proposed [46.50].

The works in [46.45, 47, 51] provide ways to incorporate new observations into the location sampling

Fig. 46.6 Application of the grid-based variant of the FastSLAM algorithm. Each particle carries its own map and the importance weights of the particles are computed based on the likelihood of the measurements given the particle's own map

process for landmarks and grid maps, based on prior work in [46.52]. This leads to an improved sampling process

$$x_t^{[k]} \approx \frac{p(z_t | m_{t-1}^{[k]}, x_t) p(x_t | x_{t-1}^{[k]}, u_t)}{p(z_t | m_{t-1}^{[k]}, x_{t-1}^{[k]}, u_t)}, \quad (46.14)$$

which incorporates the odometry and the observation at the same time. Using an improved proposal distribution leads to more accurately sampled locations. This in turn leads to more accurate maps and requires a smaller number of particles compared to approaches using the sampling process given in (46.12). This extension makes FastSLAM and especially its grid-based variants robust tools for addressing the SLAM problem.

Finally, there are approaches that aim to overcome the assumption that the observations show Gaussian characteristics. As shown in [46.47], there are several situations in which the model is nonGaussian and also multimodal. A sum of Gaussians model on a per-particle bases, however, can be efficiently considered in the particle filter and it eliminates this problem in practice without introducing additional computational demands.

The so-far developed particle filters-based SLAM systems suffer from two problems. First, the number of samples that are required to compute consistent maps is often set manually by making an *educated guess*. The larger the uncertainty that the filter needs to represent during mapping, the more critical becomes this

parameter. Second, nested loops combined with extensive re-visits of previously mapped areas can lead to particle depletion, which in turn may prevent the system from estimating a consistent map. Adaptive resampling strategies [46.45], particles sharing maps [46.50], or filter backup approaches [46.53] improve the situation but cannot eliminate this problem in general.

46.2.3 Graph-Based Optimization Techniques

A third family of algorithms solves the SLAM problem through nonlinear sparse optimization. They draw their intuition from a graphical representation of the SLAM problem and the first working solution in robotics was proposed in [46.54]. The graph-based representation used here is closely related to a series of papers [46.55–64]. We note that most of the earlier techniques are offline and address the full SLAM problem. In more recent years, new incremental versions that effectively re-use the previously computed solution have been proposed such as [46.65–67].

The basic intuition of graph-based SLAM is as follows. Landmarks and robot locations can be thought of as nodes in a graph. Every consecutive pair of locations x_{t-1}, x_t is tied together by an edge that represents the information conveyed by the odometry reading u_t . Further edges exist between the nodes that correspond to locations x_t and landmarks m_i , assuming that at time t the robot sensed landmark i . Edges in this graph are

soft constraints. Relaxing these constraints yields the robot's best estimate for the map and the full path.

The construction of the graph is illustrated in Fig. 46.7. Suppose at time $t = 1$, the robot senses landmark m_1 . This adds an arc in the (yet highly incomplete) graph between x_1 and m_1 . When caching the edges in a matrix format (which happens to correspond to a quadratic equation defining the resulting constraints), a value is added to the elements between x_1 and m_1 , as shown on the right hand side of Fig. 46.7a.

Now suppose the robot moves. The odometry reading u_2 leads to an arc between nodes x_1 and x_2 , as shown in Fig. 46.7b. Consecutive application of these two basic steps leads to an graph of increasing size, as illustrated in Fig. 46.7c. Nevertheless this graph is *sparse*, in that each node is only connected to a small number of other nodes (assuming a sensor with limited sensing range). The number of constraints in the graph is (at worst) *linear* in the time elapsed and in the number of nodes in the graph.

Fig. 46.7a–c Illustration of the graph construction. The (a) diagram shows the graph, the (b) the constraints in matrix form. (a) Observation 1s landmark m_1 . (b) Robot motion from x_1 to x_2 . (c) Several steps later

If we think of the graph as a spring-mass model [46.60], computing the SLAM solution is equivalent to computing the state of minimal energy of this model. To see, we note that the graph corresponds to the log-posterior of the full SLAM problem (46.4)

$$\log p(X_T, m \mid Z_T, U_T). \quad (46.15)$$

Without derivation, we state that this logarithm is of the form

$$\begin{aligned} \log p(X_T, m \mid Z_T, U_T) \\ = \text{const} + \sum_t \log p(x_t \mid x_{t-1}, u_t) \\ + \sum_t \log p(z_t \mid x_t, m), \end{aligned} \quad (46.16)$$

assuming independence between the individual observations and odometry readings. Each constraint of the form $\log p(x_t \mid x_{t-1}, u_t)$ is the result of exactly one robot motion event, and it corresponds to an edge in the graph. Likewise, each constraint of the form $\log p(z_t \mid x_t, m)$ is the result of one sensor measurement, to which we can also find a corresponding edge in the graph. The SLAM problem is then simply to find the mode of this equation, i.e.,

$$X_T^*, m^* = \underset{X_T, m}{\operatorname{argmax}} \log p(X_T, m \mid Z_T, U_T). \quad (46.17)$$

Without derivation, we note that under the Gaussian noise assumptions, which was made in the point-landmark example, this expression resolves to the following quadratic form

$$\begin{aligned} \log p(X_T, m \mid Z_T, U_T) = \text{const} \\ + \sum_t \underbrace{[x_t - g(x_{t-1}, u_t)]^T R_t^{-1} [x_t - g(x_{t-1}, u_t)]}_{\text{odometry reading}} \\ + \sum_t \underbrace{[z_t - h(x_t, m)]^T Q_t^{-1} [z_t - h(x_t, m)]}_{\text{feature observation}}. \end{aligned} \quad (46.18)$$

This quadratic form yields a sparse system of equations and a number of efficient optimization techniques can be applied. Common choices include direct methods such as sparse Cholesky and QR decomposition, or iterative ones such as gradient descent, conjugate gradient, and others. Most SLAM implementations rely on iteratively linearizing the functions g and h , in which case the objective in (46.18) becomes quadratic in all of its variables.

Extensions to support an effective correction of large-scale graphs are hierarchical methods. One of

the first is the ATLAS framework [46.25], which constructs a two-level hierarchy combining a Kalman filter that operates in the lower level and a global optimization at the higher level. Similar to that, Hierarchical SLAM [46.68] is a technique for using independent local maps, which are merged in case of re-visiting a place. A fully hierarchical approach has been presented in [46.65]. It builds a multilevel pose-graph and employs an incremental, lazy optimization scheme that allows for optimizing large graphs and at the same time can be executed at each step during mapping. An alternative hierarchical approach is [46.69], which recursively partitions the graph into multiple-level submaps using the nested dissection algorithm.

When it comes to computing highly accurate environment reconstructions, approaches that do not only optimize the poses of the robot but also each individual measurement of a dense sensor often provide better results. In the spirit of bundle adjustment [46.4], approaches for laser scanners [46.70] and Kinect cameras [46.71] have been proposed.

The graphical paradigm can be extended to handle the data association problems as we can integrate additional knowledge on data association into (46.18). Suppose some oracle informed us that landmarks m_i and m_j in the map corresponded to one and the same physical landmark in the world. Then, we can either remove m_j from the graph and attach all adjacent edges to m_i , or we can add a soft correspondence constraint [46.72] of the form

$$(m_j - m_i)^T \mathbf{\Gamma} (m_j - m_i) . \quad (46.19)$$

Here $\mathbf{\Gamma}$ is 2-by-2 diagonal matrix whose coefficients determine the penalty for *not* assigning identical locations to two landmarks (hence we want $\mathbf{\Gamma}$ to be large). Since graphical methods are usually used for the full SLAM problem, the optimization can be interleaved with the search for the optimal data association.

Data association errors typically have a strong impact in the resulting map estimate. Even a small number of wrong data associations is likely to result in inconsistent map estimates. Recently, novel approaches have been proposed that are robust under a certain number of false associations. For example, [46.73, 74] propose an iterative procedure that allows for disabling constraints, an action that is associated with a cost. A generalization of this method introduced in [46.75] formulates [46.74] as a robust cost function also reducing the computational requirements. Such approaches can deal with a significant number of false associations and still provide high-quality maps. Consistency checks for loop closure hypotheses can be found in other approaches as well, both in the front-end [46.76] and in the opti-

mizer [46.77]. There has also been an extension that can deal with multimodal constraints [46.78], proposing a max-mixture representation for maintaining efficiency of the log likelihood optimizing in (46.16). As a result of that, the multimodal extension has only little impact on the runtime and can easily be incorporated in most optimizers. Also robust cost function are used for SLAM, for example pseudo Huber and several alternatives [46.75, 79–81].

Graphical SLAM methods have the advantage that they scale to much higher-dimensional maps than EKF SLAM, exploiting the sparsity of the graph. The key limiting factor in EKF SLAM is the covariance matrix, which takes space (and update time) quadratic in the size of the map. No such constraint exists in graphical methods. The update time of the graph is constant, and the amount of memory required is linear (under some mild assumptions). A further advantage of graph-based methods over the EKF is their ability to constantly re-linearize the error function which often leads to better results. Performing the optimization can be expensive, however. Technically, finding the optimal data association is suspected to be an NP-hard problem, although in practice the number of plausible assignments is usually small. The continuous optimization of the log likelihood function in (46.18) depends among other things on the number and size of loops in the map. Also the initialization can have a strong impact on the result and a good initial guess can simplify the optimization substantially [46.8, 82, 83].

We note that the graph-based paradigm is very closely linked to information theory, in that the soft constraints constitute the information the robot has on the world (in an information-theoretic sense [46.92]). Most methods in the field are offline and they optimize for the entire robot path. If the robot path is long, the optimization may become cumbersome. Over the last five years, however, incremental optimization techniques have been proposed that aim at providing a sufficient but not necessarily perfect model of the environment at every point in time. This allows a robot to make decisions based on the current model, for example, to determine exploration goals. In this context, incremental variants [46.93, 94] of stochastic gradient descent techniques [46.8, 91] have been proposed that estimate which part of the graph requires re-optimization given new sensor data. Incremental methods [46.66, 79, 95] in the smoothing and mapping framework can be executed at each step of the mapping process and achieve the performance by variable ordering and selective re-linearization. As also evaluated in [46.96] for the SLAM problem, variable ordering impacts the performance of the optimization. Others use hierarchical data structures [46.89] and pose-graphs [46.97] combined with

Table 46.1 Recent open-source graph-based SLAM implementations

Name	Comment
Dynamic covariance scaling (DCS) [46.75]	Optimization with a robust cost function for dealing with outliers
g^2o [46.80]	Integrated into g^2o
	Flexible and easily extendable optimization framework for SLAM
	Comes with different optimization approaches and error functions
	Supports external plugins
GTSAM2.1 [46.79]	Flexible optimization framework for SLAM and SFM structure from motion
	Implements direct and iterative optimization techniques
	Implements smoothing and mapping (SAM), iSAM, and iSAM2
	Implements bundle adjustment for Visual SLAM and SFM
HOG-Man [46.65]	Incremental optimization approach via hierarchical pose graphs and lazy optimization
	Requires pose-graphs with full rank constraints
iSAM2 [46.66]	General incremental nonlinear optimization with variable elimination
	Variable re-ordering to retain sparsity
	On-demand re-linearization of selected variables
KinFu (KinectFusion reimplemented)	Open source reimplementation of KinectFusion [46.84] within the point cloud library (PCL)
	Dense and highly accurate reconstruction using a Kinect camera
	Currently limited to medium sized rooms
MaxMixture [46.78]	Optimization for multimodal constraints and outliers
	Robust to outliers
	Plugin for g^2o
Parallel tracking and mapping (PTAM) [46.85]	System for tracking a hand-held monocular camera and observed features
RGBD-SLAM [46.86]	Operates on comparably small workspaces
	Kinect-frontend for HOG-Man and g^2o
	Fairly standard combination of SURF matching and RANSAC
ScaViSLAM [46.87]	SLAM system for stereo and Kinect-style cameras
	Combines local bundle adjustment with sparse global optimization for on-the-fly processing
SLAM6-D [46.88]	SLAM system that operates on point clouds from 3-D laser data
	Applies iterative closest point algorithm (ICP) and global relaxation
Sparse surface adjustment (SSA) [46.70, 71]	Optimizes robot poses and proximity sensor data jointly
	Provides smooth surface estimates
	Assumes a range sensor (e.g., laser scanner, Kinect, or similar)
TreeMap [46.89]	Incremental optimization approach
	Update in $O(\log N)$ time
	Provides only a mean estimate
TORO [46.90]	Optimization approach that extends stochastic gradient descent (SGD) [46.91]
	Robust under bad initial guesses
	Recovers quickly from large errors but slow convergence at minimum
	Assumes that constraints have roughly spherical covariance matrices
	Provides only a mean estimate
Vertigo [46.74]	Switchable constraints for robust optimization
	Plugin for g^2o

a lazy optimization for on-the-fly mapping [46.65]. As an alternative to global methods, relative optimization approaches [46.98] aim at computing locally consistent geometric maps but only topological maps on the global scale. Hybrid approaches [46.87] seek to combine the best of both worlds.

There also exists a number of cross-overs that manipulate the graph online so as to factor out past robot location variables. The resulting algorithms are filters [46.25, 33, 99, 100], and they tend to be intimately related to information filter methods. Many of the original attempts to decompose EKF SLAM representations into smaller submaps to scale up are based

on motivations that are not dissimilar to the graphical approach [46.27, 28, 101].

Recently, researchers addressed the problem of long-term operation and frequent revisits of already mapped terrain. To avoid densely connected pose-graphs that lead to slow convergence behavior, the robot can switch between SLAM and localization, can merge nodes to avoid a growth of the graph [46.90, 102], or can discard nodes or edges [46.32, 103–105].

Graphical and optimization-based SLAM algorithm are still subject of intense research and the paradigm scales to maps large numbers of nodes [46.25, 55, 57, 59, 63–65, 89, 90, 106, 107]. Arguably, the graph-based

paradigm has generated some of the largest **SLAM** maps ever built. Furthermore, the **SLAM** community started to release flexible optimization frameworks and **SLAM** implementations under open source licenses to support further developments and to allow for efficient comparisons, (Table 46.1). Especially the optimization frameworks [46.66, 79, 80] are flexible and powerful state of the art tools for developing graph-based **SLAM** systems. They can be either used as a *black box* or can be easily extended through plugins.

46.2.4 Relation of Paradigms

The three paradigms just discussed cover the vast majority of work in the field of **SLAM**. As discussed, **EKF SLAM** comes with a computational hurdle that poses serious scaling limitations and the linearization may lead to inconsistent maps. The most promising extensions of **EKF SLAM** are based on building local submaps; however, in many ways the resulting algorithms resemble the graph-based approach.

Particle filter methods sidestep some of the issues arising from the natural inter-feature correlations in the map – which hindered the **EKF**. By sampling from robot poses, the individual landmarks in the map

become independent, and hence are decorrelated. As a result, FastSLAM can represent the posterior by a sampled robot pose, and many local, independent Gaussians for its landmarks. The particle representation offers advantages for **SLAM** as it allows for computationally efficient updates and for sampling over data associations. On the negative side, the number of necessary particles can grow very large, especially for robots seeking to map multiple nested loops.

Graph-based methods address the full **SLAM** problem, hence are in the standard formulation not online. They draw their intuition from the fact that **SLAM** can be modeled by a sparse graph of soft constraints, where each constraint either corresponds to a motion or a measurement event. Due to the availability of highly efficient optimization methods for sparse nonlinear optimization problems, graph-based **SLAM** has become the method of choice for building large-scale maps. Recent developments have brought up several graph-based methods for incremental map building that can be executed at every time step during navigation. Data association search can be incorporated into the basic mathematical framework and different approaches that are even robust under wrong data associations are available today.

46.3 Visual and RGB-D SLAM

A popular and important topic in recent years has been Visual **SLAM** – the challenge of building maps and tracking the robot pose in full 6-DOF using data from cameras [46.108] or RGB-D (Kinect) sensors [46.86, 109]. Visual sensors offer a wealth of information that enables the construction of rich 3-D models of the world. They also enable difficult issues such as loop-closing to be addressed in novel ways using appearance information [46.110]. Visual **SLAM** is anticipated to be a critical area for future research in perception for robotics, as we seek to develop low-cost systems that are capable of intelligent physical interaction with the world.

Attempting **SLAM** with monocular, stereo, omnidirectional, or RGB-D cameras raises the level-of-difficulty of many of the **SLAM** components, such as data association and computational efficiency, described above. A key challenge is robustness. Many visual **SLAM** applications of interest, such as augmented reality [46.85], entail handheld camera motions, which present greater difficulties for state estimation, in comparison to the motion of a wheeled robot across a flat floor.

Visual navigation and mapping was a key early goal in the mobile robotics community [46.111, 112], but

early approaches were hampered by the lack of sufficient computational resources to handle massive video data streams. Early approaches were typically based on extended Kalman filters [46.113–116], but did not compute the full covariance for the feature poses and camera trajectory, resulting in a loss of consistency. Visual **SLAM** is closely related to the structure from motion (**SFM**) problem in computer vision [46.4, 5]. Historically, **SFM** was primarily concerned with off-line batch processing, whereas **SLAM** seeks to achieve a solution for online operation, suitable for closed-loop interaction of a robot or user with its environment. In comparison to laser scanners, cameras provide a fire hydrant of information, making online processing nearly impossible until recent increases in computation have become available.

Davison was an early pioneer in developing complete visual **SLAM** systems, initially using a real-time active stereo head [46.121] that tracked distinctive visual features with a full covariance **EKF** approach. Subsequent work developed the first real-time **SLAM** system that operated with a single freely moving camera as the only data source [46.23, 122]. This system could build sparse, room-size maps of indoor scenes at 30 Hz frame-rate in real-time, a notable historical achievement

Fig. 46.8 (a) A 2-km path and 50 000 frames estimated for the New College Dataset (after [46.117]) using relative bundle adjustment (after [46.98]). (b) the relative bundle adjustment solution is easily improved by taking FAB-MAP (after [46.118]) loop-closures into account – this is achieved without global optimization (after [46.119]). Sibley et al. advocate that relative metric accuracy and topological consistency are the requirements for autonomous navigation, and these are better achieved using a relative manifold representation instead of using a conventional single Euclidean representation [46.120]

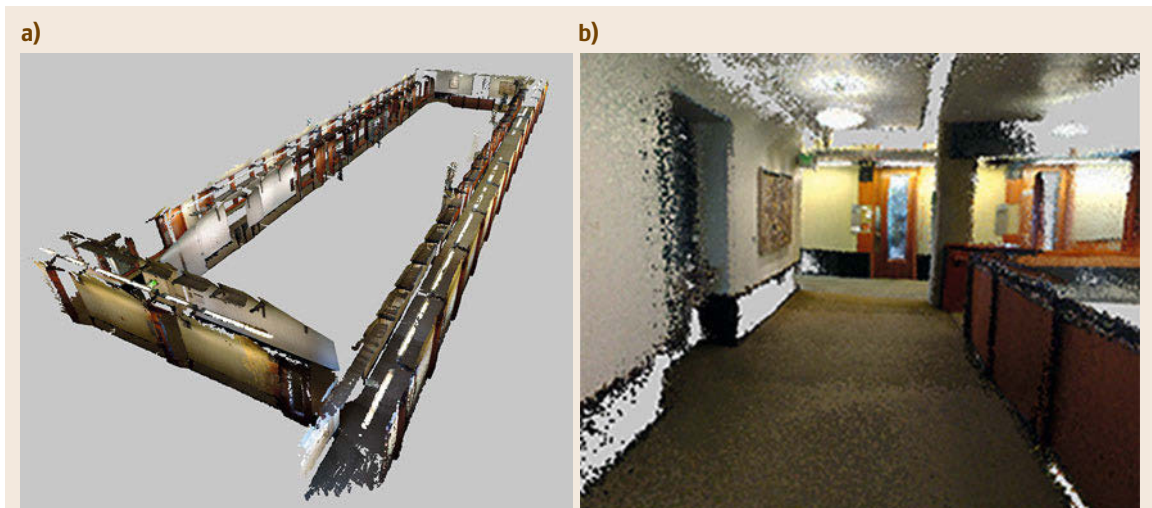

Fig. 46.9 (a) 3-D Model and (b) close-up view of a corridor environment in the Paul G. Allen building at University of Washington built from Kinect data (after [46.109]; image courtesy of Peter Henry, University of Washington)

in visual SLAM research. A difficulty encountered with initial monocular SLAM [46.23] was coping with the initialization of points that were far away from the camera, due to nonGaussian distributions of such feature locations resulting from poor depth information. This limitation was overcome in [46.24], introducing an inverse depth parameterization for monocular SLAM, a key development for enabling a unified treatment of initialization and tracking of visual features in real-time.

A milestone in creating robust visual SLAM systems was the introduction of keyframes in parallel tracking and mapping (PTAM) [46.85], which separated the tasks of keyframe mapping and localization into parallel threads, improving robustness and performance for online processing. Keyframes are now a mainstream concept for complexity reduction in visual SLAM systems. Related approaches using keyframes include [46.87, 123–126]. The work

in [46.108] analyzes the tradeoffs between filtering and keyframe-based bundle adjustment in visual SLAM, and concluded that keyframe bundle adjustment outperforms filtering, as it provides the most accuracy per unit of computing time.

As pointed out by Davison and other researchers, an appealing aspect of visual SLAM is that camera measurements can provide odometry information, and indeed visual odometry is a key component of modern SLAM systems [46.127]. Here, [46.128] and [46.129] provide an extensive tutorial of techniques for visual odometry, including feature detection, feature matching, outlier rejection, and constraint estimation, and trajectory optimization. Finally, a publicly available visual odometry library [46.130] that is optimized for efficient operation on small unmanned aerial vehicles is available today.

Visual information offers a tremendous source of information for loop closing, not present in the canonical 2-D laser SLAM systems developed in the early 2000s. The work in [46.110] was one of the first to employ techniques for visual object recognition [46.131] to location recognition. More recently FAB-MAP [46.118, 132] has demonstrated appearance-only place recognition at large scale, mapping trajectories with a length of 1000 km. Combining a bag-of-features approach with a probabilistic place model and Chow–Liu tree inference leads to place recognition that is robust against perceptual aliasing while remaining computationally efficient. Other work on place recognition includes [46.133], which combines bag-of-words loop closing with tests of geometrical consistency based on conditional random fields (Fig. 46.8).

The techniques described above have formed the basis for a number of notable large-scale SLAM systems developed in recent years. A 2008 special issue of the IEEE Transactions on Robotics provides a good snapshot of recent state-of-the-art SLAM techniques [46.135]. Other notable recent examples include [46.98, 119, 126, 136–138]. The idea of employing relative bundle adjustment [46.98] to compute a full maximum likelihood solution in an online fashion, even for loop closures, by employing a manifold representation that does not attempt to enforce Euclidean constraints results in maps that can be computed at high frame rate (see also Fig. 46.8). Finally, view-based mapping systems [46.126, 136, 137] aim at large-scale and/or life-long visual mapping based on the pose graph optimization techniques described above in Section 46.2.3.

Several compelling 3-D mapping and localization have been created in recent years with RGB-D (Kinect) sensors. The combination of direct range measurements with dense visual imagery can enable dramatic im-

provements in mapping and navigation systems for indoor environments. State-of-the-art RGB-D SLAM systems include [46.109] and [46.86]. Figure 46.9 shows examples of the output of these systems.

Other researchers aim at exploiting the surface properties of scanned environments to correct for sen-

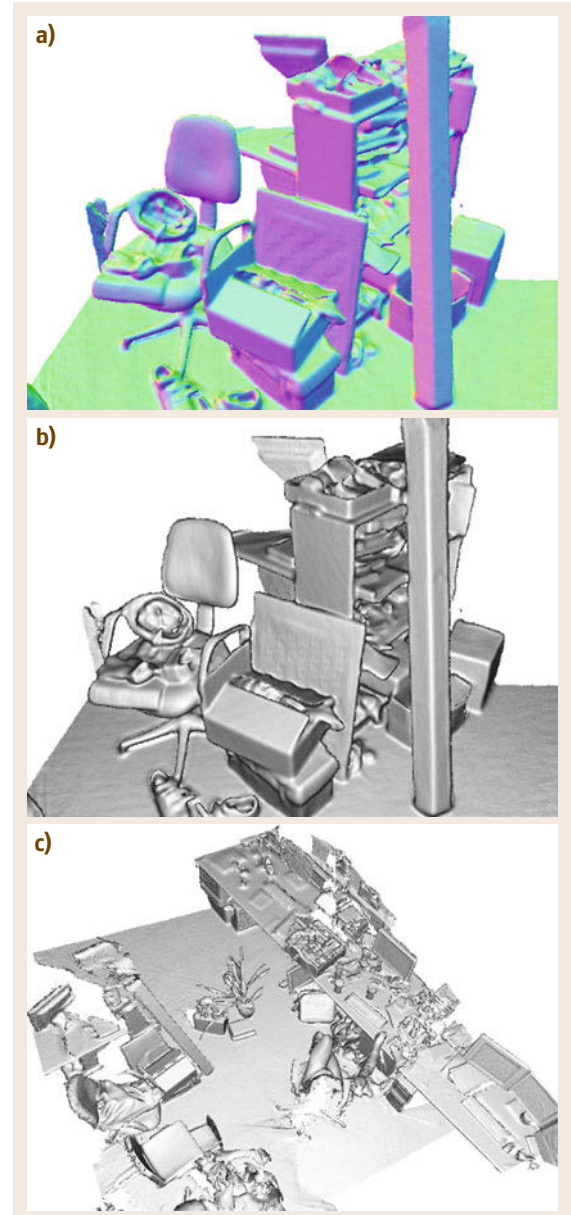

Fig. 46.10a–c Results obtained with KinectFusion (after [46.134]). (a) A local scene as a normal map and (b) as a Phong-shaded rendering. The (c) image depicts a larger scene (image courtesy of Richard Newcombe, Imperial College London)

Fig. 46.11 Spatially extended KinectFusion output produced in real-time with Kintinuous (after [46.139])

sor noise of range sensors such as the Kinect [46.71]. They jointly optimize the poses of the sensor and the positions of the surface points measured and iteratively refine the structure of the error function by recomputing the data associations after each optimization, resulting in accurate smooth models of the environment.

An emerging area for future research is the development of fully dense processing methods that exploit recent advances in commodity graphical processing unit (GPU) technology. Kinect-based dense tracking and mapping, a fully-dense method for small-scale visual tracking and reconstruction is described in [46.140]. Dense modeling and tracking are achieved

via highly parallelized operations on commodity GPU hardware to yield a system that outperforms previous methods such as PTAM for challenging camera trajectories. Dense methods offer an interesting perspective from which to address long-standing problems, such as visual odometry, from a fresh perspective, without requiring explicit feature detection and matching [46.141]. KinectFusion [46.84, 134] is a dense modeling system that tracks the 3-D pose of a handheld Kinect while concurrently reconstructing high-quality scene 3-D models in real-time. See Fig. 46.10 for an example. KinectFusion has been applied to spatially extended environments in [46.139, 142]. An example is shown in Fig. 46.11.

46.4 Conclusion and Future Challenges

This chapter has provided an introduction into SLAM, which is defined as the problem faced by a mobile platform roaming an unknown environment, and seeking to localize itself while concurrently building a map of the environment. The chapter discussed three main paradigms in SLAM, which are based on the extended Kalman filter, particle filters, and graph-based sparse optimization techniques, and then described recent progress in Visual/Kinect SLAM.

The following references provide an in-depth tutorial on SLAM and much greater depth of coverage on the details of popular SLAM algorithms. Furthermore, several implementations of popular SLAM systems, including most of the approaches listed in Table 46.1, can be found in online resources such as <http://www.openslam.org> or in the references [46.6, 9, 21, 62].

The considerable progress in SLAM in the past decade is beyond doubt. The core state estimation at

the heart of **SLAM** is now quite well understood, and a number of impressive implementations have been developed, including several widely used open source software implementations and some commercial projects. None-the-less, a number of open research challenges remain for the general problem of robotic mapping in complex and dynamic environments over extended periods of time, including robots sharing, extending, and revising previously built models, efficient failure recovery, zero user intervention, and operation on resource-constrained systems. Another exciting area for the future is the further development of fully dense visual mapping systems exploiting the latest advances in **GPU** hardware development.

An ultimate goal is to realize the challenge of *persistent* navigation and mapping – the capability for a robot to perform **SLAM** robustly for days, weeks, or months at a time with minimal human supervision, in complex and dynamic environments. Taking the limit as $t \rightarrow \infty$ poses difficult challenges to most current algorithms; in fact, most robot mapping and navigation algorithms are doomed to fail with the passage of time, as errors inevitably accrue. Despite recent encouraging solutions [46.102, 105], more research is needed for techniques that can recover from mistakes and enable robots to deal with changes in the environment and enabling a long-term autonomous existence.

47. Motion Planning and Obstacle Avoidance

Javier Minguez, Florant Lamiraux, Jean-Paul Laumond

This chapter describes motion planning and obstacle avoidance for mobile robots. We will see how the two areas do not share the same modeling background. From the very beginning of motion planning, research has been dominated by computer sciences. Researchers aim at devising well-grounded algorithms with well-understood completeness and exactness properties.

The challenge of this chapter is to present both nonholonomic motion planning (Sects. 47.1–47.6) and obstacle avoidance (Sects. 47.7–47.10) issues. Section 47.11 reviews recent successful approaches that tend to embrace the whole problem of motion planning and motion control. These approaches benefit from both nonholonomic motion planning and obstacle avoidance methods.

The introduction of nonholonomic constraints has entailed revisiting these algorithms via the introduction of differential geometry materials. Such a combination has been made possible for certain classes of systems, the so-called small-time controllable ones. It remains that the underlying hypothesis of motion planning algorithms is the knowledge of a global and accurate map of the environment. More than that the considered system is a formal system of equations that does not account for the entire physical system: uncertainties in the world or system modeling are not considered. Such hypotheses are too strong in practice. This is why other complementary research has been done in parallel in a more pragmatic but realistic manner. Such research deals with obstacle avoidance. The problem here is not to deal with complicated systems like a car with multiple trailers. The considered systems are much simpler with respect to their geometric shape. The problem considers sensor-based motions to face the physical issues of a real system navigating in a real world better than motion planning algorithms. How can we *navigate* toward a goal in a cluttered environment when the obstacles to avoid have just been discovered in real time? This is the question that obstacle avoidance addresses. The appearance of mobile robots in the late 1960s early 1970s initiated a new research domain: autonomous navigation. It is interesting to note that the first navigation systems were published at the very first International Joint Conferences on Artificial Intelligence (IJCAI 1969). These systems were based on seminal ideas, which have been very fruitful in the development of robot motion planning algorithms. For instance, in 1969, the mobile robot Shakey used a grid-based approach to model and explore the environment [47.1], in 1977 Jason used a visibility graph built from the corners

of the obstacles [47.2], and in 1979 Hilare decomposed the environment into collision-free convex cells [47.3].

In the late 1970s, studies of robot manipulators popularized the notion of the configuration space of a mechanical system [47.4]. In the configuration space the *piano* becomes a point. The motion planning problem for a mechanical system was thus reduced to finding a path for a point in the configuration space. The way was open to extending the seminal ideas and to developing new and well-grounded algorithms (see Latombe's book [47.5]).

One decade later, the notion of nonholonomic systems (also borrowed from mechanics) appeared in the literature [47.6] on robot motion planning through the problem of car parking. This problem had not been solved by the pioneering works on mobile robot navigation. Nonholonomic motion planning then became an attractive research field [47.7].

Besides this research effort in path planning, work was initiated in order to make robots move out of their initially artificial environments where the world was cylindrical and composed of wooden vertical boards. Robots started to move in laboratory buildings, with people walking around. Inaccurate localization, uncertain and incomplete maps of the world, and unexpected moving or static obstacles made roboticists aware of the gap between planning a path and executing a motion. Since then the domain of obstacle avoidance has been very active.

In the 2000s a lot of effort has been made toward the integration of motion planning and obstacle avoidance. This effort was stimulated by the DARPA Urban challenge competition. The most successful integration was done by the Carnegie Mellon University team, who won the competition [47.8].

47.1 Nonholonomic Mobile Robots: Where Motion Planning Meets Control Theory

Nonholonomic constraints are nonintegrable linear constraints over the velocity space of a system. For instance, the rolling without slipping constraint of a differentially-driven mobile robot (Fig. 47.1) is linear with respect to the velocity vector (vector of linear and angular velocities) of the differentially-driven robot

and is non integrable (it cannot be integrated into a constraint over the configuration variables). As a consequence, a differentially-driven mobile robot can go anywhere but not following any trajectory. Other types of nonholonomic constraints arise when considering second-order differential equations such as the conser-

vation of inertial momentum. A number of papers investigate the famous falling cat problem or free-floating robots in space [47.7]. This chapter is devoted to nonholonomic constraints for mobile robots with wheels.

While the constraints due to obstacles are expressed directly in the configuration space, that is a manifold, nonholonomic constraints are expressed in the tangent space. In the presence of a linear kinematic constraint, the first question that naturally arises is: *does this constraint reduce the space reachable by the system?* This question can be answered by studying the structure of the distribution spanned by the Lie algebra of the control system.

Even in the absence of obstacles, planning admissible motions (i. e., that satisfy the kinematic constraints) for a nonholonomic system between two configurations is not an easy task. Exact solutions have been proposed

only for some classes of systems but a lot of systems remain without exact solution. In the general case, however, approximate solutions can be used.

The motion planning problem for a nonholonomic system can be stated as follows: given a map of the environment with obstacles in the workspace, a robot subject to nonholonomic constraints, an initial configuration and a goal configuration, find an admissible collision-free path between the initial and goal configurations. Solving this problem requires taking into account both the configuration space constraints due to obstacles and the nonholonomic constraints. The tools developed to address this issue thus combine motion planning and control theory techniques. Such a combination is possible for the class of so-called small-time controllable systems due to topological arguments (Theorem 47.2 in Sect. 47.3).

47.2 Kinematic Constraints and Controllability

In this section, we give the main definition of controllability, using *Sussman's* terminology [47.9].

47.2.1 Definitions

Let us denote by CS the configuration space of dimension n of a given mobile robot and by \mathbf{q} the configuration of this robot. If the robot is mounted on wheels, it is subject to kinematic constraints, linear in the velocity vector

$$\omega_i(\mathbf{q})\dot{\mathbf{q}} = 0, \quad i \in \{1, \dots, k\}.$$

We assume that these constraints are linearly independent for any \mathbf{q} . Equivalently, for each \mathbf{q} , there exists $m = n - k$ linearly independent vectors $f_1(\mathbf{q}), \dots, f_m(\mathbf{q})$ such that the above constraints are equivalent to

$$\exists (u_1, \dots, u_m) \in \mathbb{R}^m, \quad \dot{\mathbf{q}} = \sum_{i=1}^m u_i f_i(\mathbf{q}). \quad (47.1)$$

Let us note that the choice of vectors $f_i(\mathbf{q})$ is not unique. Fortunately, all the following developments are valid whatever choice we make. Moreover, if the linear constraints are smooth, vector fields f_1, \dots, f_m can be chosen smooth with respect to \mathbf{q} . We assume this condition from now on.

Let us define by \mathcal{U} a compact subset of \mathbb{R}^m . We denote by Σ the control system defined by (47.1), with $(u_1, \dots, u_m) \in \mathcal{U}$.

Definition 47.1

A local and small-time controllability:

1. Σ is *locally controllable about configuration \mathbf{q}* iff the set of configurations reachable from \mathbf{q} by an admissible trajectory contains a neighborhood of \mathbf{q} .
2. Σ is *small-time controllable about configuration \mathbf{q}* iff the set of configurations reachable from \mathbf{q} by an admissible trajectory in time less than T contains a neighborhood of \mathbf{q} for any T .

f_1, \dots, f_m are called *control vector fields* of Σ . A system's small-time controllable about each configuration is said to be *small-time controllable*.

47.2.2 Controllability

Checking the controllability properties of a system requires the analysis of the control Lie algebra associated with the system. Let us illustrate in an informal way what the Lie bracket of two vector fields is. Consider two basic motions: *go along a straight line* and *turn on the spot*, supported by vector fields denoted by f and g , respectively. Now consider the following combination: go forward during a time t , turn clockwise during the same time t , go backward during the same time t and then turn counterclockwise during the time t . The system reaches a configuration that is not the starting one. Of course when t tends to 0 the goal configuration is very close to the starting one. The direction indicated by such goal configurations when t tends to 0 correspond to a new vector field, which is the Lie bracket of f and g . In a more mathematical formulation, the Lie

bracket $[f, g]$ of two vector fields f and g is defined as being the vector field $\partial f \cdot g - \partial g \cdot f$. The k -th coordinate of $[f, g]$ is

$$[f, g][k] = \sum_{i=1}^n \left(g[i] \frac{\partial}{\partial x_i} f[k] - f[i] \frac{\partial}{\partial x_i} g[k] \right).$$

The following theorem [47.10] gives a powerful result for symmetric systems (a system is said to be symmetric when \mathcal{U} is symmetric with respect to the origin).

Theorem 47.1

A symmetric system is small-time controllable about configuration \mathbf{q} iff the rank of the vector space spanned by the family of vector fields f_i together with all their brackets is n at \mathbf{q} .

Checking the Lie algebra rank condition (LARC) on a control system consists in trying to build a basis of the tangent space from a basis (e.g., a P. Hall family) of the free Lie algebra spanned by the control vector fields. An algorithm is proposed in [47.11, 12].

47.2.3 Example: The Differentially-Driven Mobile Robot

To illustrate the notions developed in this section, we consider the differentially-driven mobile robot displayed in Fig. 47.1. The configuration space of this robot is $\mathbb{R}^2 \times S^1$, and a configuration can be represented by $\mathbf{q} = (x, y, \theta)$ where (x, y) is the position in the horizontal plane of the center of the wheel axis of the robot and θ the orientation with respect to the x -axis. The rolling without slipping kinematic

Fig. 47.1 A differentially-driven mobile robot is subject to one linear kinematic constraint, due to the rolling without slipping constraint of the wheel axis

constraint

$$-\dot{x} \sin \theta + \dot{y} \cos \theta = 0$$

is linear with respect to the velocity vector $(\dot{x}, \dot{y}, \dot{\theta})$. Therefore, the subspace of admissible velocities is spanned by two vector fields, for instance,

$$f_1(\mathbf{q}) = \begin{pmatrix} \cos \theta \\ \sin \theta \\ 0 \end{pmatrix} \quad \text{and} \quad f_2(\mathbf{q}) = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}. \quad (47.2)$$

The Lie bracket of these two vector fields is

$$f_3(\mathbf{q}) = \begin{pmatrix} \sin \theta \\ -\cos \theta \\ 0 \end{pmatrix}.$$

This implies that about any configuration \mathbf{q} , the rank of the vector space spanned by $f_1(\mathbf{q}), f_2(\mathbf{q}), f_3(\mathbf{q})$ is 3 and, therefore, that the differentially-driven mobile robot is small-time controllable.

47.3 Motion Planning and Small-Time Controllability

Motion planning raises two problems: the first one addresses the *existence* of a collision-free admissible path; this is the decision problem. The second one addresses the *computation* of such a path; this is the complete problem.

47.3.1 The Decision Problem

From now on, we assume that the set of collision-free configurations is an open subset. This implies that contact configurations are assumed in collision.

Theorem 47.2

The existence of a collision-free admissible path for a symmetric small-time controllable mobile robot between two configurations is equivalent to the existence

of a collision-free (not necessarily admissible) path between these configurations.

Proof: Let us consider a not necessarily admissible collision-free path between two configurations \mathbf{q}_1 and \mathbf{q}_2 as a continuous mapping Γ from interval $[0, 1]$ into the configuration space CS such that:

1. $\Gamma(0) = \mathbf{q}_1, \Gamma(1) = \mathbf{q}_2$,
2. for any $t \in [0, 1]$, $\Gamma(t)$ is collision free.

Point 2 implies that for any t there exists a neighborhood $U(t)$ of $\Gamma(t)$ included in the collision-free subset of the configuration space.

Let us denote by $\varepsilon(t)$ the bigger lower bound of the time to collision of all the trajectories starting from

$\Gamma(t)$. As the control vector (u_1, \dots, u_m) remains in the compact set \mathcal{U} , $\varepsilon(t) > 0$.

As the system is small-time controllable about $\Gamma(t)$, the set reachable from $\Gamma(t)$ in time less than $\varepsilon(t)$ is a neighborhood of $\Gamma(t)$, which we denote by $V(t)$.

The collection $\{V(t), t \in [0, 1]\}$ is an open covering of the compact set $\{\Gamma(t), t \in [0, 1]\}$. Therefore, we can extract a finite covering, $\{V(t_1), \dots, V(t_l)\}$, where $t_1 = 0 < t_2 < \dots < t_{l-1} < t_l = 1$ such that for any i between 1 and $l-1$, $V(t_i) \cap V(t_{i+1}) \neq \emptyset$. For each i between 1 and $l-1$, we choose one configuration r_i in $V(t_i) \cap V(t_{i+1})$. As the system is symmetric, there exists an admissible collision-free path between $q(t_i)$ and r_i and between r_i and $q(t_{i+1})$. The concatenation of these paths is a collision-free admissible path between q_1 and q_2 . ■

47.3.2 The Complete Problem

In the former section, we have established that the decision problem, i.e., determining whether there exists a collision-free admissible path between two configurations, is equivalent to determining whether the configurations lie in the same connected component of the collision-free configuration space. In this section we present the tools necessary to solve the complete problem. These tools blend ideas from the classical motion planning problem addressed in Chap. 7 and from open loop control theory, but require specific developments that we are going to present in the next section. Two main approaches have been devised in order to plan admissible collision-free motions for non-holonomic systems. The first one proposed by [47.13] exploits the idea of the proof of Theorem 47.2 by recursively approximating a not necessarily admissible collision-free path by a sequence of feasible paths. The second approach replaces the local method of probabilistic roadmap method (PRM) algorithms (Chap. 7) by a local steering method that connects configuration pairs by admissible paths (📺 VIDEO 707).

Both approaches use a steering method. Before briefly describing them, we give the definition of a local steering method.

Definition 47.2

A local steering method for system Σ is a mapping

$$S_{\text{loc}} : CS \times CS \rightarrow C_{\text{pw}}^1([0, 1], CS)$$

$$(q_1, q_2) \mapsto S_{\text{loc}}(q_1, q_2)$$

5 where $S_{\text{loc}}(q_1, q_2)$ is a piecewise continuously differentiable curve in CS satisfying the following properties:

1. $S_{\text{loc}}(q_1, q_2)$ satisfies the kinematic constraints associated to Σ ,
2. $S_{\text{loc}}(q_1, q_2)$ connects q_1 to q_2 : $S_{\text{loc}}(q_1, q_2)(0) = q_1$, $S_{\text{loc}}(q_1, q_2)(1) = q_2$.

Approximation of a Not Necessarily Admissible Path

A not necessarily admissible collision-free path $\Gamma(t)$, $t \in [0, 1]$ connecting two configurations and a local steering method S_{loc} being given, the approximation algorithm proceeds recursively, by calling function approximation defined by Algorithm 47.1 with input Γ , 0 and 1.

Algorithm 47.1

approximation function: inputs are a path Γ and two abscissas t_1 and t_2 along this path

```

if  $S_{\text{loc}}(\Gamma(t_1), \Gamma(t_2))$  collision free then
    return  $S_{\text{loc}}(\Gamma(t_1), \Gamma(t_2))$ 
else
    return concat(approximation( $\Gamma, t_1, (t_1+t_2)/2$ ),
                  approximation( $\Gamma, (t_1+t_2)/2, t_2$ ))
end if

```

Sampling-Based Roadmap Methods

Most sampling-based roadmap methods as described in Chap. 6 can be adapted to nonholonomic systems by replacing the connection method between pairs of configurations by a local steering method. This strategy is rather efficient for PRM algorithms. For the rapidly-exploring random tree (RRT) method, the efficiency strongly depends on the metric used to choose the nearest neighbor. The distance function between two configurations needs to account for the length of the path returned by the local steering method to connect these configurations [47.14].

47.4 Local Steering Methods and Small-Time Controllability

The approximation algorithm described in the former section is recursive and raises the completeness question: does the algorithm finish in finite time or may it fail to find a solution?

A sufficient condition for the approximation algorithm to find a solution in a finite number of iterations is that the local steering method accounts for small-time controllability.

Definition 47.3

A local steering method S_{loc} accounts for the small-time controllability of system Σ iff

For any $\mathbf{q} \in CS$, for any neighborhood U of \mathbf{q} , there exists a neighborhood V of \mathbf{q} such that for any $\mathbf{r} \in V$, $S_{\text{loc}}(\mathbf{q}, \mathbf{r})([0, 1]) \subset U$.

In other words, a local steering method accounts for the small-time controllability of a system if it produces paths getting closer to the configurations it connects when these configurations get closer to each other.

This property is also sufficient for probabilistic completeness of roadmap sampling-based methods.

47.4.1 Local Steering Methods Accounting for Small-Time Controllability

Constructing a local steering method that accounts for small-time controllability is a difficult task that has been achieved only for a few classes of systems. Most mobile robots studied in the domain of motion planning are wheeled mobile robots towing trailers or not.

Steering Using Optimal Control

The simplest system, namely the differentially-driven robot presented in Sect. 47.2.3 with bounded velocities or the so-called *Reeds and Shepp* [47.15] car with bounded curvature have the same control vector fields (47.2). The difference lies in the domain of the control variables:

- $-1 \leq u_1 \leq 1, |u_2| \leq |u_1|$ for RS car,
- $|u_1| + b|u_2| \leq 1$ for the differentially-driven robot,

where b is half of the distance between the right and left wheels. For these systems, a local steering method accounting for small-time controllability can be constructed using optimal control theory. For any admissible path defined over an interval I of one of these systems, we define a length as follows

$$\int_I |u_1| \quad \text{for the RS car ,}$$

$$\int_I |u_1| + b|u_2| \quad \text{for the differentially-driven robot .}$$

The length of the shortest path between two configurations in both cases defines a metric over the configuration space. The synthesis of the shortest paths, i. e., the determination of the shortest path between any pair of configurations was achieved by [47.16] for the RS car and later by [47.17] for the differentially-driven robot. Figure 47.2 shows a representation of the balls corresponding to these metrics.

Optimal control naturally defines a local steering method that associates a shortest path between these configurations to any pair of configurations. Let us note that the shortest path is unique between most pairs of configurations. A general result states that the collection of balls of radius $r > 0$ centered about \mathbf{q} induced by nonholonomic metrics constitutes an increasing collection of neighborhoods of \mathbf{q} , the intersection of which is $\{\mathbf{q}\}$. This property directly implies that local steering methods based on shortest paths account for small-time controllability.

The main advantage of optimal control is that it provides both a local steering method and a distance metric consistent with the steering method. This makes the steering methods well suited for path planning algorithms designed for holonomic systems and using a distance function, such as RRT (Chap. 7), for instance.

Unfortunately, the synthesis of the shortest paths has been realized only for the two simple systems described in this section. For more complex systems, the problem remains open.

The main drawback of the shortest path-based steering methods described in this section is that input

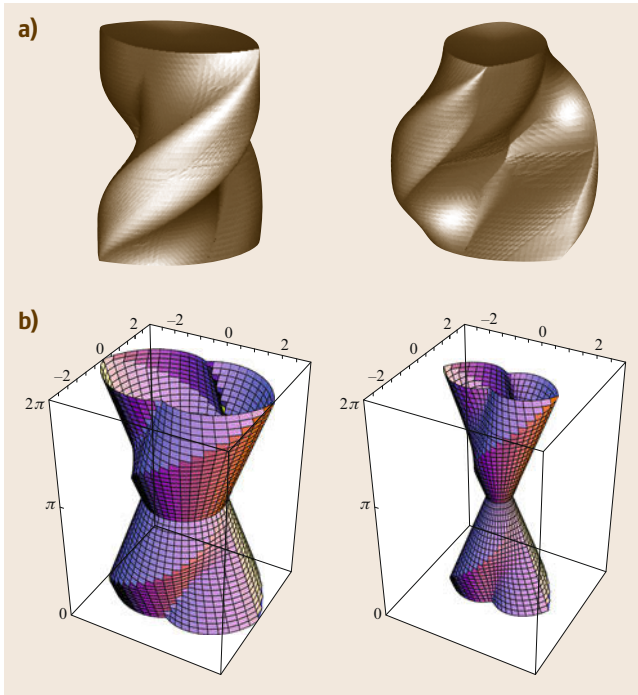

Fig. 47.2 (a) Two perspective views of an RS (Reeds and Shepp) ball: set of configurations reachable by a path of length less than a given distance for the Reeds and Shepp car. (b) Perspective views of two DD (differentially driven) balls: set of configurations reachable by a path of a length less than a given distance for the differentially-driven robot. Orientation θ is represented on z -axis

functions are not continuous. This requires an additional step to compute a time-parameterization of the paths before motion execution. Along this time-parameterization, input discontinuities force the robot to stop. For instance, to follow two successive arcs of circles of opposite curvature a mobile robot needs to stop between the arcs of circle in order to ensure continuity of the linear and angular velocities u_1 and u_2 .

Steering Chained-Form Systems

Some classes of systems can be put into the form called the *chained-form* system by a change of variable

$$\dot{z}_1 = u_1, \quad (47.3)$$

$$\dot{z}_2 = u_2, \quad (47.4)$$

$$\dot{z}_3 = z_2 u_1, \quad (47.5)$$

$$\vdots$$

$$\dot{z}_n = z_{n-1} u_1. \quad (47.6)$$

Let us consider the following inputs [47.18]

$$\begin{cases} u_1(t) = a_0 + a_1 \sin \omega t, \\ u_2(t) = b_0 + b_1 \cos \omega t \\ \quad + \dots + b_{n-2} \cos(n-2)\omega t. \end{cases} \quad (47.7)$$

Let $Z^{\text{start}} \in \mathbb{R}^n$ be a starting configuration. Each $z_i(1)$ can be computed from the coordinates of Z^{start} and parameters $(a_0, a_1, b_0, b_1, \dots, b_{n-2})$. For a given $a_1 \neq 0$ and a given configuration Z^{start} , the mapping from $(a_0, b_0, b_1, b_2, b_3)$ to $Z(1)$ is a C^1 -diffeomorphism at the origin; the system is then invertible. For n smaller or equal to 5, parameters $(a_0, b_0, b_1, \dots, b_{n-2})$ can be analytically computed from the coordinates of the two configurations Z^{start} and Z^{goal} . The corresponding sinusoidal inputs steer the system from Z^{start} to Z^{goal} . The shape of the path only depends on parameter a_1 . Each value of a_1 thus defines a local steering method denoted by $S_{\text{sin}}^{a_1}$. None of these steering methods account for small-time controllability since for any $Z \in \mathbb{R}^n$, $S_{\text{sin}}^{a_1}(Z, Z)([0, 1])$ is not reduced to $\{Z\}$. To construct a local steering method accounting for small-time controllability from the collection of $S_{\text{sin}}^{a_1}$, we need to make a_1 depend on the configurations Z_1 and Z_2 that we want to connect

$$\lim_{Z^2 \rightarrow Z^1} a_1(Z^1, Z^2) = 0,$$

$$\lim_{Z^2 \rightarrow Z^1} a_0[Z^1, Z^2, a_1(Z^1, Z^2)] = 0,$$

$$\lim_{Z^2 \rightarrow Z^1} b_i[Z^1, Z^2, a_1(Z^1, Z^2)] = 0.$$

Such a construction is achieved in [47.19].

Steering Feedback-Linearizable Systems

The concept of *feedback linearizability* (or differential flatness) was introduced by Fliess et al. [47.20, 21].

A system is said to be *feedback linearizable* if there exists an output (i. e., function of the state, input and input derivatives) called the *linearizing output*, such that the state and the input of the system is a function of the linearizing output and its derivatives. The dimension of the linearizing output is the same as the dimension of the input.

Let us illustrate this notion with a simple example. We consider a differentially-driven mobile robot towing a trailer hitched on top of the wheel axis of the robot, as displayed in Fig. 47.3. The tangent to the curve followed by the center of the wheel axis of the trailer gives the orientation of the trailer. From the orientation of the trailer along the curve, we can deduce the curve followed by the center of the robot. The tangent to the curve followed by the center of the robot gives the orientation of the robot. Thus the linearizing output of this system is the center of the wheel axis of the trailer. By differentiating the linearizing output twice, we can reconstruct the configuration of the system.

Feedback linearizability is very interesting for steering purposes. Indeed, the linearizing output is not subject to any kinematic constraints. Therefore, if we know the relation between the state and the linearizing output, planning an admissible path between two configurations simply consists in building a curve in \mathbb{R}^m ,

Fig. 47.3 A differentially-driven robot towing a trailer. Hitched on top of the wheel axis of the robot is a feedback-linearizable system. The linearizing output is the center of the wheel axis of the trailer. The configuration of the system can be reconstructed by differentiating the curve $y(s)$, where s is an arc-length parameterization, followed by the linearizing output. The orientation of the trailer is given by $\tau = \arctan(\dot{y}_2/\dot{y}_1)$. The angle between the robot and the trailer is given by $\phi = -l \arctan(d\tau/ds)$. l is the length of the trailer connection

where m is the dimension of the input with differential constraints at both ends. This problem can be easily solved using, for instance, polynomials.

For two input driftless systems like Σ , the linearizing output only depends on state q . The state q depends on the linearizing output through the parameterization invariant values, namely, the linearizing output y , the orientation τ of the vector tangent to the curve followed by y and the successive derivatives of τ with respect to the curvilinear abscissa s .

Thus, the configuration of a two input feedback-linearizable driftless system of dimension n can be represented by a vector $(y, \tau, \tau^1, \dots, \tau^{n-3})$ representing the geometric properties of the curve followed by the linearizing output along an admissible path passing through the configuration.

Therefore, designing a local steering method for such a system is equivalent to associating to any pair of vectors $(y_1, \tau_1, \tau_1^1, \dots, \tau_1^{n-3})$, $(y_2, \tau_2, \tau_2^1, \dots, \tau_2^{n-3})$ a curve in the plane starting from y_1 and ending at y_2 with orientation of the tangent vector and successive derivatives with respect to s and equal to $\tau_1, \tau_1^1, \dots, \tau_1^{n-3}$ at the beginning and to $\tau_2, \tau_2^1, \dots, \tau_2^{n-3}$ at the end. This exercise is relatively easy using polynomials and transforming the boundary conditions into linear equations over the coefficients of the polynomials. However, taking into account small-time controllability is a little bit more tricky. Reference [47.22] proposes a flatness-based steering method built on convex combinations of canonical curves.

47.4.2 Equivalence Between Chained-Formed and Feedback-Linearizable Systems

In the previous section, we proposed methods to steer feedback-linearizable control systems or sys-

tems that can be put into chained-form. We now give a necessary and sufficient condition for feedback-linearizability.

Feedback-Linearizability: A Necessary and Sufficient Condition

In [47.23], *Rouchon* gives conditions to check whether or not a system is feedback-linearizable. For two-input driftless systems a necessary and sufficient condition is the following: let us define as Δ^k , $k > 0$ the collection of distributions (i.e., set of vector fields) iteratively defined by: $\Delta_0 = \text{span}\{f_1, f_2\}$, $\Delta_1 = \text{span}\{f_1, f_2, [f_1, f_2]\}$ and $\Delta_{i+1} = \Delta_i + [\Delta_i, \Delta_i]$ with $[\Delta_i, \Delta_i] = \text{span}\{[f, g], f \in \Delta_i, g \in \Delta_i\}$. A system with two-dimensional input is feedback-linearizable iff $\text{rank}(\Delta_i) = 2 + i$.

Example: The Chained-Form System

Let us consider the chained-form system defined by (47.3)–(47.6). The control vector fields of this system are

$$\begin{aligned} f_1 &= (1, 0, z_2, \dots, z_{n-1}), \\ f_2 &= (0, 1, \dots, 0), \end{aligned}$$

$\text{rank} \Delta_0 = 2$. If we compute $f_3 = [f_1, f_2] = (0, 0, 1, 0, \dots, 0)$, we note that $\text{rank} \Delta_1 = 3$. By computing $f_i = [f_1, f_{i-1}]$ for i up to n , we find a sequence $f_i = (0, \dots, 0, 1, 0, \dots, 0)$, where 1 is at position i . Therefore, $\text{rank} \Delta_i = 2 + i$ for i up to $n - 2$ and the chained-form system is feedback linearizable. This conclusion could have been drawn in a more straightforward way by noticing that the state can be reconstructed from (z_1, z_2) and its derivatives. (z_1, z_2) is thus the linearizing output of the chained-form system.

47.5 Robots and Trailers

Robotics systems studied in motion planning are mainly those composed of a mobile robot alone or towing one or several trailers. The input of these systems is two dimensional.

47.5.1 Differentially-Driven Mobile Robots

The simplest mobile robot, namely the differentially-driven mobile robot displayed in Fig. 47.1, is obviously feedback-linearizable. the trajectory of the center of the wheel axis (the linearizing output) of the robot gives

the orientation of the robot. It can thus be steered using a flatness-based local steering method.

47.5.2 Differentially-Driven Mobile Robots Towing One Trailer

The differentially-driven mobile robot towing a trailer hitched on top of the wheel axis of the robot displayed in Fig. 47.3 is feedback linearizable and the linearizing output is the center of the wheel axis of the trailer. The differentially-driven mobile robot towing a trailer with hitched kingpin (Fig. 47.4) is also feedback lineariz-

Fig. 47.4 A differentially-driven mobile robot towing a trailer with hitched kingpin is feedback linearizable

able [47.24] but the relation between linearizing output and configuration variables is more intricate

$$\begin{cases} y_1 = x_1 - b \cos \theta + L(\phi) \frac{b \sin \theta + a \sin(\theta + \phi)}{\sqrt{a^2 + b^2 + 2ab \cos \phi}}, \\ y_2 = x_2 - b \sin \theta - L(\phi) \frac{a \cos(\theta + \phi) + b \cos \theta}{\sqrt{a^2 + b^2 + 2ab \cos \phi}}, \end{cases}$$

where L is defined by the following elliptic integral

$$L(\phi) = ab \int_0^\phi \frac{\cos \sigma}{\sqrt{a^2 + b^2 + 2ab \cos(\sigma)}} d\sigma,$$

which is the linearizing output of the system. These relations together with the following ones

$$\tan \tau = \frac{a \sin(\theta + \phi) + b \sin \theta}{b \cos \theta + a \cos(\theta + \phi)},$$

$$\kappa = \frac{\sin(\phi)}{\cos \phi \sqrt{a^2 + b^2 + 2ab \cos \phi} + L(\phi) \sin(\phi)},$$

make it possible to reconstruct the configuration variables from the linearizing output and its two first derivatives.

47.5.3 Car-Like Mobile Robots

A car-like mobile robot is constituted of a fixed rear wheel axis and of two steerable front wheels, the axes of which intersect at the center of curvature (Fig. 47.5). A car-like mobile robot is kinematically equivalent to a differentially-driven mobile robot towing a trailer hitched on top of the wheel axis of the robot (Fig. 47.3): the virtual front wheel corresponds to the differentially-driven robot, while the body of the car corresponds to the trailer.

Fig. 47.5 Car-like mobile robot. The axes of the front wheels intersect at the center of curvature. The steering angle ϕ is the angle between the longitudinal axis of the car and a virtual front wheel in the middle of the two front wheels

Fig. 47.6 Bi-steerable robot. The front and rear wheels are steerable and there is a relation between the rear steering angle and the front steering angle: $\alpha = f(\phi)$

47.5.4 Bi-Steerable Mobile Robots

The bi-steerable mobile robot (Fig. 47.6) is a car with front and rear steerable wheels and with a relation between the front and rear steering angles. This system has been proved to be feedback linearizable in [47.25]. As for the mobile robot towing a trailer with hitched kingpin, the linearizing output is a moving point in the robot reference frame.

47.5.5 Differentially-Driven Mobile Robots Towing Trailers

Let us consider the differentially-driven mobile robot towing a trailer connected on top of the wheel axis of the robot, and let us add an arbitrary number of trailers,

Fig. 47.7 A truck towing a towbar trailer with hitched kingpin and a differentially-driven mobile robot towing two trailers with hitched kingpin: two open problems for exact path planning for nonholonomic systems

each one connected on top of the wheel axis of the previous one. By differentiating once the curve followed by the center of the last trailer, we get the orientation of the last trailer (this orientation coincides with the orientation of the tangent to the curve). If we know the orientation and the position of the center of the last trailer along the path, we can reconstruct the curve followed by the center of the previous trailer. Repeating this reasoning, we can reconstruct the trajectory of

the whole system by differentiating a sufficient number of times. The system is therefore feedback linearizable and the linearizing output is the center of the last trailer.

Combining the above reasoning with the systems reviewed in this section, we can build hybrid feedback-linearizable trailer systems. For instance, a differentially-driven mobile robot towing an arbitrary number n of trailers each one connected on top of the wheel axis of the previous trailer, except the last trailer with hitched kingpin is feedback linearizable. Simply consider the two last trailers as a feedback-linearizable system composed of a mobile robot with one trailer as in Fig. 47.4. The linearizing output of this system enables us to reconstruct the trajectory of the two last trailers. The center of trailer $n - 1$ is a linearizing output for the mobile robot towing the $n - 1$ last trailers.

47.5.6 Open Problems

Finally, all the systems for which we are able to plan exact motions between arbitrary pairs of configurations are included in the large class of feedback-linearizable systems. We have indeed seen that chained-form systems are also part of this class. For other systems, no exact solution has been proposed up to now. For instance, neither of the systems displayed in Fig. 47.7 is feedback linearizable. They do not satisfy the necessary condition of Sect. 47.4.2.

47.6 Approximate Methods

To deal with nonholonomic systems not belonging to any class of systems for which exact solutions exist, numerical approximate solutions have been developed. We review some of these methods in this section.

47.6.1 Forward Dynamic Programming

In [47.26] Barraquand and Latombe propose a dynamic programming approach to nonholonomic path planning. Admissible paths are generated by a sequence of constant input values, applied over a fixed interval of time δt . Starting from the initial configuration the search generates a tree: the children of a given configuration q are obtained by setting the input to a constant value and integrating the differential system over δt . The configuration space is discretized into an array of cells of equal size (i. e., hyper-parallelipeds). A child q' of a configuration q is inserted in the search tree if and only if the computed path from q to q' is collision free and q' does not belong to a cell containing an already generated

configuration. The algorithm stops when it generates a configuration belonging to the same cell as the goal (i. e., it does not necessarily reach the goal exactly).

The algorithm has been proved to be asymptotically complete with respect to both δt and the size of the cells. As a brute force method, it remains quite time consuming in practice. Its main interest is that the search is based on Dijkstra's algorithm, which allows taking into account optimality criteria such as the path length or the number of reversals. Asymptotical optimality to generate the minimum of reversals is proved for the car-like robot alone.

47.6.2 Discretization of the Input Space

In [47.27] Divelbiss and Wen propose a method to produce an admissible collision-free path for a nonholonomic mobile robot in the presence of obstacles. They restrict the set of input functions over the subspace spanned by Fourier basis over interval $[0, 1]$. An in-

put function is thus represented by a finite-dimensional vector λ . Reaching a goal configuration thus becomes a nonlinear system of equations, the unknowns of which are the coordinates λ_i 's of λ . The authors use the Newton–Raphson method to find a solution. Obstacles are defined by inequality constraints over the configuration space. The path is discretized into N samples. The noncollision constraint expressed at these sample points yields the inequality constraint over vector λ . These inequality constraints are turned into equality constraints through function g defined as

$$g(c) = \begin{cases} (1 - e^c)^2 & \text{if } c > 0, \\ 0 & \text{if } c \leq 0. \end{cases}$$

Reaching a goal configuration while avoiding obstacles thus becomes a nonlinear system of equations over vector λ again solved using the Newton–Raphson method. The method is rather efficient for short maneuvers. The main difficulty is to tune the order of the Fourier expansion.

Long motions in cluttered environments require a higher order, while motion in empty space can be solved with a low order. The authors do not mention the problem of numerical instability in the integration of the dynamic system.

47.6.3 Input-Based Rapidly Exploring Random Trees

The **RRT** algorithms described in Chap. 7 can be used without a local steering method to plan paths for nonholonomic systems. New nodes can be generated from existing nodes by applying random input functions over an interval of time [47.28]. The main difficulty consists in finding a distance function that really accounts for the distance the system needs to travel to go from one configuration to another. Moreover, the goal is never exactly reached. This latter drawback can be overcome by post-processing the path returned by **RRT** using a path deformation method, as described in [47.29].

47.7 From Motion Planning to Obstacle Avoidance

Up to now we have described motion planning techniques. Their objective is to compute a collision-free trajectory to the target configuration that complies with the vehicle constraints. They assume a perfect model of the robot and scenario. The advantage of these techniques is that they provide complete and global solutions of the problem. Nevertheless, when the surroundings are unknown and unpredictable, these techniques fail.

A complementary way to face the motion problem is obstacle avoidance. The objective is to move a vehicle towards a target location free of collisions with the obstacles collected by the sensors during motion execution. The advantage of reactive obstacle avoidance is to compute motion by introducing the sensor information within the control loop, used to adapt the

motion to any contingency incompatible with initial plans.

The main cost of considering the reality of the world during execution is locality. In this instance, if global reasoning is required, a trap situation could occur. Despite this limitation, obstacle avoidance techniques are mandatory to deal with mobility problems in unknown and evolving surroundings.

Notice that methods have been developed to combine both the global point of view of motion planning and the local point of view of obstacle avoidance. How can we consider robot perception at the planning level? This is so-called sensor-based motion planning. Several variants exist, such as the Bug algorithms initially introduced in [47.30]. However, none of them consider the practical context of nonholonomic mobile robots.

47.8 Definition of Obstacle Avoidance

Let \mathcal{A} be the robot (a rigid object) moving in the workspace \mathcal{W} , whose configuration space is CS . Let \mathbf{q} be a configuration, \mathbf{q}_t this configuration in time t , $\mathcal{A}(\mathbf{q}_t) \in \mathcal{W}$ the space occupied by the robot in this configuration. In the vehicle there is a sensor, which in \mathbf{q}_t measures a portion of the space $S(\mathbf{q}_t) \subset \mathcal{W}$ identifying a set of obstacles $\mathcal{O}(\mathbf{q}_t) \subset \mathcal{W}$.

Let \mathbf{u} be a constant control vector and $\mathbf{u}(\mathbf{q}_t)$ this control vector applied in \mathbf{q}_t during time δt . Given $\mathbf{u}(\mathbf{q}_t)$, the vehicle describes a trajectory $\mathbf{q}_{t+\delta t} = f(\mathbf{u}, \mathbf{q}_t, \delta t)$,

with $\delta t \geq 0$. Let $\mathcal{Q}_{t,T}$ be the set of configurations of the trajectory followed from \mathbf{q}_t with $\delta t \in [0, T]$, a given time interval. $T > 0$ is called the *sampling period*. Let $F: CS \times CS \rightarrow \mathbb{R}^+$ be a function that evaluates the progress of one configuration to another.

47.8.1 Obstacle Avoidance Problem

Let $\mathbf{q}_{\text{target}}$ be a target configuration. Then, in time t_i the robot \mathcal{A} is in \mathbf{q}_{t_i} , where a sensor measurement

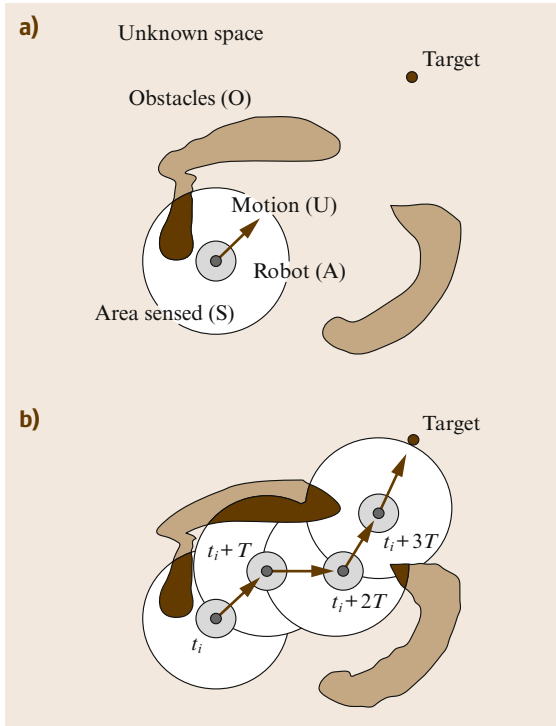

Fig. 47.8 (a) Obstacle avoidance problem consists of computing motion control that avoids collisions with the obstacles gathered by the sensors whilst driving the robot towards the target location. (b) The result of applying this technique at each time is a sequence of motions that drive the vehicle free of collisions to the target

is obtained $S(\mathbf{q}_i)$, and thus an obstacle description $\mathcal{O}(\mathbf{q}_i)$.

47.9 Obstacle Avoidance Techniques

We describe here a taxonomy of obstacle avoidance techniques and some representative methods. First there are two groups, methods that compute the motion in one step and methods that do it in more than one. Methods of one step directly reduce the sensor information to motion control. There are two types:

- The *heuristic* methods were the first techniques used to generate motion based on sensors. The majority of this work was derived in classic planning methods and will not be described here. See [47.1, 30–33] for some representative work.
- The methods of *physical analogies* assimilate the obstacle avoidance to a known physical problem. We discuss here the potential field methods [47.34, 35]. Other works are variants adapted to uncertain

The objective is to compute a motion control \mathbf{u}_i , such that (i) the trajectory generated is free of collisions with the obstacles $\mathcal{A}(\mathcal{Q}_{t_i, T}) \cap \mathcal{O}(\mathbf{q}_i) = \emptyset$; and (ii) it makes the vehicle progress to the target location $F(\mathbf{q}_i, \mathbf{q}_{\text{target}}) < F(\mathbf{q}_{i+T}, \mathbf{q}_{\text{target}})$.

The result of solving this problem at each sample time (Fig. 47.8a) is a sequence of motion controls $\{\mathbf{u}_1 \dots \mathbf{u}_n\}$ computed in execution time that avoids the obstacles gathered by the sensors, while making the vehicle progress towards the target location in each configuration $\{\mathbf{q}_{t_1} \dots \mathbf{q}_{\text{target}}\}$ (Fig. 47.8b). Notice that the motion problem is a global problem. The obstacle avoidance methods are local and iterative techniques to address this problem. The disadvantage of locality (trap situations) is counteracted with the advantage of introducing the sensory information within the control cycle (to take into account the reality of the world in execution).

There are at least three aspects that affect the development of an obstacle avoidance method: the avoidance technique, the type of robot-sensor and the type of scenario. These subjects correspond to the next three sections. First, we describe the obstacle avoidance techniques (Sect. 47.9). Second, we discuss the techniques to adapt a given obstacle avoidance method to work on a vehicle taking into account the shape, kinematics, and dynamics (Sect. 47.10). The sensory processing is detailed in Chaps. 5 and 25 of this book. Finally, the usage of an obstacle avoidance technique on a vehicle in a given scenario is highly dependent on the scenario nature (static or dynamic, unknown or known, structured or not, or its size, for example). Usually, this problem is associated with the integration of planning and obstacle avoidance (Sect. 47.11).

models [47.36] or that use other analogies [47.37–39].

Methods with more than one step compute some intermediate information, which is processed next to obtain the motion:

- The methods of *subset of controls* compute an intermediate set of motion controls, and next they choose one of them as a solution. There are two types: (i) methods that compute a subset of motion directions. We describe here the vector field histogram (VFH) [47.40] and the obstacle restriction method [47.41] (see [47.42] for three-dimensional (3-D) workspaces). Another method is the steer angle field approach [47.43]. (ii) Methods that com-

pute a subset of velocity controls. We describe here the dynamic window approach (DWA) [47.44] and velocity obstacles [47.45] (see [47.46] for moving obstacles). Another method based on similar principles but developed independently is the curvature velocity method [47.47].

- Finally, there are methods that compute some *high-level information* such as intermediate information, which is translated next in motion. We describe the basic versions of the nearness diagram navigation [47.48, 49]. The reader is directed to [47.50–52] for further improvements.

All the methods outlined here have advantages and disadvantages, depending on the navigation context, like uncertain worlds, motion at high speeds, motion in confined or troublesome spaces, etc. Unfortunately there is no metric available to quantitatively measure the performance of the methods. However, for an experimental comparison in terms of their intrinsic problems see [47.48].

47.9.1 Potential Field Methods

The potential field method (PFM) uses an analogy in which the robot is a particle that moves in the configuration space under the influence of a force field. While the target location exerts a force that attracts the particle F_{att} , the obstacles exert repulsive forces F_{rep} . At each time t_i , the motion is computed to follow the direction of the artificial force induced by the sum of both potentials $F_{\text{tot}}(q_{t_i}) = F_{\text{att}}(q_{t_i}) + F_{\text{rep}}(q_{t_i})$ (the most promising motion direction), Fig. 47.9.

Example

$$F_{\text{att}}(q_{t_i}) = K_{\text{att}} \mathbf{n}_{q_{\text{target}}} \quad (47.8)$$

$$F_{\text{rep}}(q_{t_i}) = \begin{cases} K_{\text{rep}} \sum_j \left(\frac{1}{d(q_{t_i}, p_j)} - \frac{1}{d_0} \right) \mathbf{n}_{p_j} & \text{if } d(q_{t_i}, p_j) < d_0, \\ 0 & \text{otherwise} \end{cases} \quad (47.9)$$

where K_{att} and K_{rep} are the constants of the forces, d_0 is the influence distance of the obstacles p_j , q_{t_i} is the current vehicle configuration and $\mathbf{n}_{q_{\text{target}}}$ and \mathbf{n}_{p_j} are the unitary vectors that point from q_{t_i} to the target and each obstacle p_j . From $F_{\text{tot}}(q_{t_i})$, the control u_i can be obtained with a position or force control [47.53].

This is the classic version, where the potentials only depend on the current vehicle configuration. Complementarily the generalized potentials depend also on the instantaneous robot velocity and vehicle accelerations.

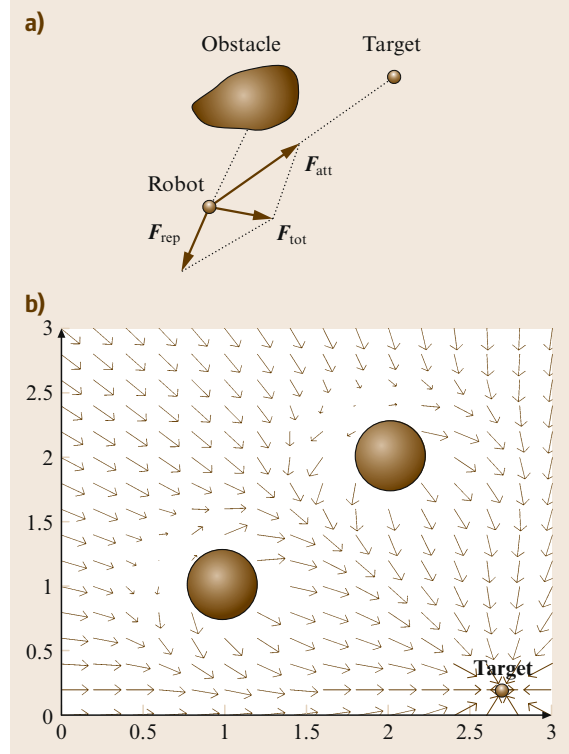

Fig. 47.9 (a) Computation of the motion direction with a potential field method. The target attracts the particle F_{att} while the obstacle exerts a repulsive force F_{rep} . The resulting force F_{tot} is the most promising motion direction. (b) Motion directions computed in each point of the space with the classic method

Example

$$F_{\text{rep}}(q_{t_i}) = \begin{cases} K_{\text{rep}} \sum_j \left(\frac{a \dot{q}_{t_i}}{[2ad(q_{t_i}, p_j) - \dot{q}_{t_i}^2]} \right) \mathbf{n}_{p_j} \cdot \mathbf{n}_{\dot{q}_{t_i}} & \text{if } \dot{q}_{t_i} > 0, \\ 0 & \text{otherwise} \end{cases} \quad (47.10)$$

where \dot{q}_{t_i} is the current robot velocity, $\mathbf{n}_{\dot{q}_{t_i}}$ the unitary vector pointing in the direction of the robot velocity, and a is the maximum vehicle acceleration. This expression arises when the repulsive potential is defined as the inverse of the difference between the estimated time until a collision takes place and the time needed to stop the robot until full backward acceleration. Notice how the repulsive only affect in the direction of motion of the vehicle, as opposed to the classic potential. For a comparison of the classic and generalized versions,

and the relation with the way to compute the motion controls next, see [47.53]. This method is widely used because it is easy to understand and due to its clear mathematic formalism.

47.9.2 Vector Field Histogram

The vector field histogram (VFH) solves the problem in two steps by computing a set of candidate motion directions and then selecting one of them.

Candidate Set of Directions

Firstly the space is divided into sectors from the robot location. The method uses a polar histogram H constructed around the robot, where each component represents the obstacle polar density in the corresponding sector. The function that maps the obstacle distribution in sector k on the corresponding component of the histogram $h^k(q_{t_i})$ is

$$h^k(q_{t_i}) = \int_{\Omega_k} P(p)^n \cdot \left(1 - \frac{d(q_{t_i}, p)}{d_{\max}}\right)^m dp. \quad (47.11)$$

The dominion of integration is $\Omega_k = \{p \in \mathcal{W} \mid p \in k \wedge d(q_{t_i}, p) < d_0\}$. The density $h^k(q_{t_i})$ is proportional to the probability $P(r)$ that a point was occupied by an obstacle, and to a factor that increases when the distance to the point decreases.

Typically the resulting histogram has peaks (directions with high density of obstacles) and valleys (directions with low density). The set of candidate directions is the set of adjacent components with density lower than a given threshold, and closest to the component that contains the target direction. This set of components (sectors) is called the selected valley, and represents a set of candidate directions (Fig. 47.10).

Motion Computation

The objective of the next step is to choose a direction of this set. The strategy is to apply three heuristics that depend on the component that contains the target or on the size of the selected valley. The cases are checked in sequence:

1. Case 1: goal sector in the selected valley. Solution: $k_{\text{sol}} = k_{\text{target}}$, where k_{target} is the sector that contains the goal location.
2. Case 2: goal sector not in the selected valley and number of sectors of the valley greater than m . Solution: $k_{\text{sol}} = k_i \pm m/2$, where m is a fixed number of sectors and k_i the sector of the valley closer to the k_{target} .

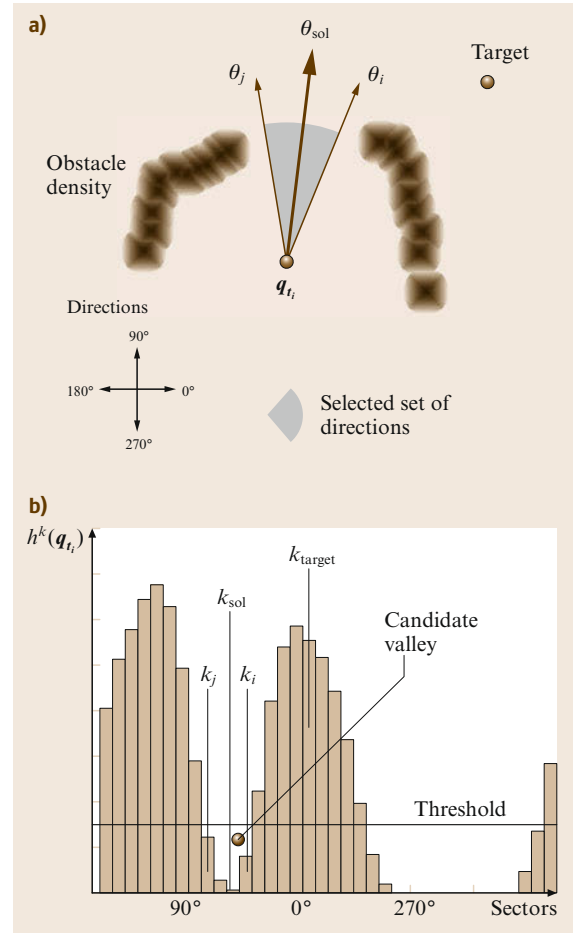

Fig.47.10a,b Computation of the motion direction θ_{sol} with VFH. (a) Robot and obstacle occupancy distribution. (b) The candidate valley is the set of adjacent components with values lower than the threshold. The navigation case is Case 3, since the sector of the target k_{target} is not in the valley and the number of sectors is lower than a fixed quantity m ($m = 8$, i. e., 45°). Thus the solution is $k_{\text{sol}} = (k_i + k_j)/2$, whose bisector is θ_{sol} in (a). The bisectors of k_i and k_j are θ_i and θ_j , respectively

3. Case 3: goal sector not in the selected valley and number of sectors of the valley lower or equal to m . Solution: $k_{\text{sol}} = (k_i + k_j)/2$, where k_i and k_j are the extreme sectors of the valley.

The result is a component or sector k_{sol} , whose bisector is the direction solution θ_{sol} . The velocity v_{sol} is inversely proportional to the distance to the closest obstacle. The control is $u_i = (v_{\text{sol}}, \theta_{\text{sol}})$.

VFH is a method formulated to work with probabilistic obstacle distributions, and thus, it is well adapted to work with uncertain sensors as ultrasonic sonars.

47.9.3 The Obstacle Restriction Method

The obstacle restriction method (ORM) solves the problem in three steps, where the result of the two first steps is a set of candidate motion directions. The first step is to compute an instantaneous subgoal if necessary. The second one associates a motion constraint to each obstacle and joins them next to compute the set of desirable directions. The last step is an strategy to compute the motion given this set.

Instantaneous Target Selection

This step computes a subgoal when is better to direct the motion towards a given zone of the space (which ameliorates the situation to reach the goal latter), rather than directly towards the goal itself. The subgoals are located in between obstacles or in the edge of an obstacle (Fig. 47.11a). Next, the process is to check with a local algorithm whether the goal can be reached from the robot location. If it is not, then the closest reachable subgoal to the goal is selected. To check if a point can be reached, there is a local algorithm that computes the existence of a local path that joins two locations [47.48].

Let x_a and x_b be two locations of the space, R the robot radius, and L a list of obstacle points, where p_i is an obstacle of the list. Let \mathcal{A} and \mathcal{B} be the two semiplanes divided by the line that joins x_a and x_b . Then, if for all the points of L , $d(p_j, p_k) > 2R$ (with $p_j \in \mathcal{A}$ and $p_k \in \mathcal{B}$), there is a collision free path that joins both locations. If this condition is not satisfied, then there is no local path (although a global one could exist). The interesting result is when the result is positive, since the guarantee that one point can be reached from the other exists.

The result of the process is the goal or an instantaneous subgoal (from now this location is called the target location). Note that this process is general and can be used as a preprocess step by other methods to instantaneously validate the goal location or to compute an instantaneous subgoal to drive the vehicle.

Candidate Set of Directions

For each obstacle i a set of not desirable directions for motion S_{nD}^i is computed (motion constraint). This set is the union of two subsets S_1^i and S_2^i . S_1^i represents the side of the obstacle not suitable to do the avoidance and S_2^i is an exclusion area around the obstacle (Fig. 47.11b). The motion constraint for the obstacle is the union of both sets $S_{nD}^i = S_1^i \cup S_2^i$. The set of desired directions of motion is the complementary $S_D = [-\pi, \pi] \setminus S_{nD}$, where $S_{nD} = \cup_i S_{nD}^i$.

Motion Computation

The final step is to select a direction of motion. There are three cases that depend on the set of desirable direc-

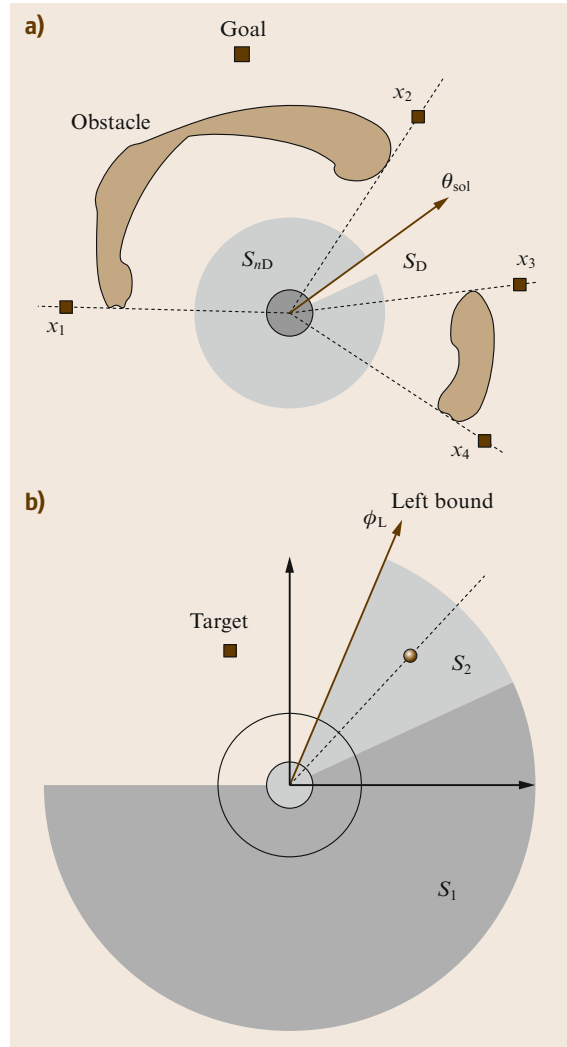

Fig. 47.11 (a) Distribution of the subgoals x_i . The selected instantaneous target location is x_2 . The set of candidate directions is S_{nD} and the solution is θ_{sol} (the second case). (b) The two sets of not desirable directions S_1 and S_2 for a given obstacle

tions S_D and on the target direction θ_{target} . The cases are checked in sequence:

1. Case 1: $S_D \neq \emptyset$ and $\theta_{target} \in S_D$. Solution: $\theta_{sol} = \theta_{target}$.
2. Case 2: $S_D \neq \emptyset$ and $\theta_{target} \notin S_D$. Solution: $\theta_{sol} = \theta_{lim}$, where θ_{lim} is the direction of S_D closest to θ_{target} .
3. Case 3: $S_D = \emptyset$. Solution: $\theta_{sol} = (\phi_{lim}^l + \phi_{lim}^r)/2$, where ϕ_{lim}^l and ϕ_{lim}^r are the directions of S_{D_l} and S_{D_r} closer to θ_{target} (S_{D_l} and S_{D_r} are the set of desirable

directions of obstacles on the left and right-hand sides of the target, respectively).

The result is a direction of motion solution θ_{sol} . The velocity v_{sol} is inversely proportional to the distance to the closest obstacle. The control is $\mathbf{u}_i = (v_{\text{sol}}, \theta_{\text{sol}})$. This is a geometric-based method based on cases. The advantage is that it has been demonstrated to address effective motion in confined spaces.

47.9.4 Dynamic Window Approach

The dynamic window approach (DWA) (VIDEO 712) is a method that solves the problem in two steps, by computing as intermediate information a subset of the control space \mathcal{U} . For simplicity, we consider a motion control such as translational and rotational velocity (v, w) ; \mathcal{U} is defined by

$$\mathcal{U} = \{ (v, w) \in \mathbb{R}^2 \setminus \begin{aligned} &v \in [-v_{\max}, v_{\max}] \wedge \\ &w \in [-w_{\max}, w_{\max}] \} . \end{aligned} \quad (47.12)$$

Set of Candidate Controls

The candidate set of controls \mathcal{U}_R contains the controls: (i) within the maximum velocities of the vehicle \mathcal{U} , (ii) that generate safe trajectories \mathcal{U}_A , and (iii) that can be reached within a short period of time given the vehicle accelerations \mathcal{U}_D . The set \mathcal{U}_A contains the admissible controls. These controls can be canceled before collision by applying the maximum deceleration (a_v, a_w)

$$\mathcal{U}_A = \left\{ (v, w) \in \mathcal{U} \mid v \leq \sqrt{2d_{\text{obs}}a_v} \wedge w \leq \sqrt{2\theta_{\text{obs}}a_w} \right\} , \quad (47.13)$$

where d_{obs} and θ_{obs} are the distance to the obstacle and the orientation of the tangent to the trajectory in the obstacle. The set \mathcal{U}_D contains the controls reachable in a short period

$$\mathcal{U}_D = \{ (v, w) \in \mathcal{U} \setminus \begin{aligned} &v \in [v_o - a_v T, v_o + a_v T] \wedge \\ &w \in [w_o - a_w T, w_o + a_w T] \} , \end{aligned} \quad (47.14)$$

where $\dot{\mathbf{q}}_{t_i} = (v_o, w_o)$ is the current velocity.

The resulting subset of controls is (Fig. 47.12)

$$\mathcal{U}_R = \mathcal{U} \cap \mathcal{U}_A \cap \mathcal{U}_D . \quad (47.15)$$

Motion Computation

The next step is to select one control $\mathbf{u}_i \in \mathcal{U}_R$. The problem is set out as the maximization of an objective

Fig. 47.12 Subset of controls $\mathcal{U}_R = \mathcal{U} \cap \mathcal{U}_A \cap \mathcal{U}_D$, where \mathcal{U} contains the controls within the maximum velocities, \mathcal{U}_A the admissible controls, and \mathcal{U}_D the controls reachable in a short period of time

function

$$G(\mathbf{u}) = \alpha_1 \cdot \text{Goal}(\mathbf{u}) + \alpha_2 \cdot \text{Clearance}(\mathbf{u}) + \alpha_3 \cdot \text{Velocity}(\mathbf{u}) . \quad (47.16)$$

This function is a compromise among $\text{Goal}(\mathbf{u})$ that favors velocities that offer progress to the goal, $\text{Clearance}(\mathbf{u})$ that favors velocities far from the obstacles, and $\text{Velocity}(\mathbf{u})$ that favors high speeds. The solution is the control \mathbf{u}_i that maximizes this function.

DWA solves the problem in the control space using information of the vehicle dynamics, thus the method is well adapted to work on vehicles with slow dynamic capabilities or that work at high speeds.

47.9.5 Velocity Obstacles

The method of velocity obstacles (VO) solves the problem in two steps, by computing as intermediate information a subset of the \mathcal{U} . The framework is equal to that of DWA. The difference is that the computation of the set of safe trajectories \mathcal{U}_A takes into account the velocity of the obstacles, which is described next.

Let \mathbf{v}_i be the velocity of obstacle i (which became enlarged with the vehicle radius occupying an area B_i) and \mathbf{u} a given vehicle control. The set of colliding relative velocities is called *collision cone*

$$CC_i = \{ \mathbf{u}_i \mid \lambda_i \cap B_i \neq \emptyset \} , \quad (47.17)$$

where λ_i is the direction of the unitary vector $\mathbf{u}_i = \mathbf{u} - \mathbf{v}_i$. The *velocity obstacle* is this set in a common absolute system of reference

$$VO_i = CC_i \oplus \mathbf{v}_i , \quad (47.18)$$

where \oplus is the Minkowski vector sum. The set of unsafe trajectories is the union of the velocity obstacles for

Fig. 47.13 Subset of not safe controls $\tilde{U}_A = VO_1 \cup VO_2$. A control vector out of this velocity generates a collision-free motion with the moving obstacles

each moving obstacle $\tilde{U}_A = \cup_i VO_i$ (Fig. 47.13). The advantage of this method is that takes into account the velocity of the obstacles; thus it is well suited in dynamic scenarios.

47.9.6 Nearness Diagram Navigation

This method is more a methodology to design obstacle avoidance methods rather than a method in itself. Near-

ness diagram navigation (ND) is an obstacle avoidance method obtained with a geometric implementation following this methodology. The idea behind is to employ a divide and conquer strategy based on situations to simplify the obstacle avoidance problem following the situated-activity paradigm [47.54]. First, there is a set of situations that represent all the cases among robot locations, obstacles, and target locations. Also, for each case there is a motion law associated with it. During the execution phase, at time t_i one situation is identified and the corresponding law is used to compute the motion.

Situations

The situations are represented in a binary decision tree. The selection of a situation depends on the obstacles $\mathcal{O}(q_{t_i})$, on the robot location q_{t_i} and target q_{target} . The criteria are based on high-level entities, like a security distance around the robot bounds and a motion area (that identifies suitable areas of motion). For example, one criterion is if there are obstacles within the security zone. Another is if the motion area is large or narrow. The result is only one situation, since by definition and representation (binary decision tree) the set of situations is complete and exclusive (Fig. 47.14).

Actions

Associated to any situation there is an action that computes the motion to adapt the behavior to the case

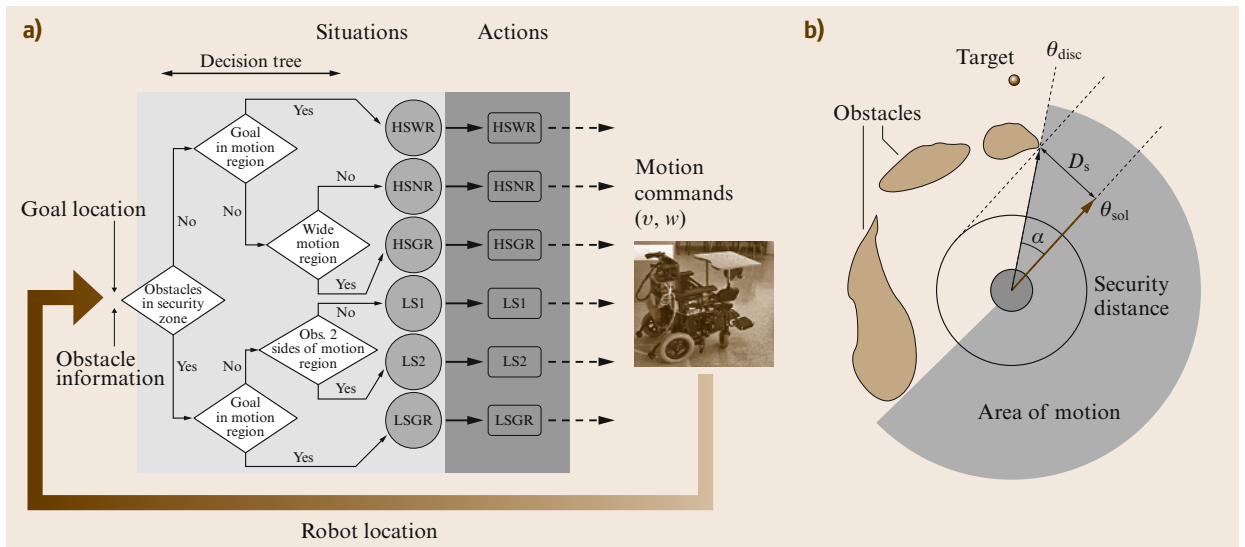

Fig. 47.14 (a) Design diagram of the method. Given the obstacle information and the target location, one situation is identified given some criteria. Next the associated action is executed computing the motion. (b) Example of computation of the solution of the ND (geometric implementation). The first step is to identify the situation. There are no obstacles closer than the security distance D_s . Next q_{target} is not within the motion area. Third, the motion area is wide. With these three criteria we identify the current situation, HSWR. In this situation, the associated action computes the control as $u_i = (v_{\text{sol}}, \theta_{\text{sol}})$, where v_{sol} is the maximum velocity and θ_{sol} is computed as a deviation α from the limit direction θ_{disc} of the motion area closer to the target direction

represented by each situation. At a high level the actions describe the behavior desired in each situation. For example, one situation is when there are no obstacles within a security area and the goal is within the motion area (HSGR). The solution is to *move towards the goal*. Another situation is when there are no obstacles within a security area, and the goal is not within the motion area but is wide (HSWR). The solution is to *move towards the limit of the motion area but clearing the security area of obstacles*.

47.10 Robot Shape, Kinematics, and Dynamics in Obstacle Avoidance

There are three aspects of the vehicle that have to be taken into account during the obstacle avoidance process: shape, kinematics, and dynamics. The shape with the kinematics is a geometric problem that involves the representation of the vehicle configurations in collision, given the admissible trajectories $\mathcal{Q}_{t,\infty}$. The dynamics involves the accelerations and temporal considerations, and is derived in two aspects: (i) choosing a control reachable in a short period of time T given the current velocity $\dot{\mathbf{q}}_{t_i}$ and the maximum accelerations. (ii) Taking the braking distance into account, so that after a control execution, the vehicle can always stop before collision by applying the maximum deceleration (improving safety).

The problem of shape, kinematics, and dynamics in obstacle avoidance has been taken into account from three different points of view:

1. Designing a way to incorporate the constraints within the method (Sect. 47.9.4)
2. Developing techniques that abstract the vehicle aspects from the application of the method [47.55–58]
3. By techniques that break down the problem into subproblems and incorporate the aspects in sequence [47.59–61] after method usage.

47.10.1 Techniques that Abstract Vehicle Aspects

These techniques are based on constructing an abstraction layer between the aspects of the vehicle and the obstacle avoidance method, in such a way that when the method is applied its solutions already take into account these aspects [47.55–58]. We consider here vehicles whose elementary paths obtained under execution of constant controls can be approximated by circular arcs (for example, a differential-drive robot, synchro-drive, or a tri-cycle). To simplify, a control is translational and rotational velocity $\mathbf{u} = (v, w)$. The set of reachable controls \mathcal{U}_A given the current velocity $\dot{\mathbf{q}}_{t_i} = (v_0, w_0)$ and the maximum accelerations (a_v, a_w) is obtained by (47.14).

The interesting aspect of this method is that it employs a *divide and conquer* strategy to solve the navigation. As a consequence, it simplifies the difficulty of the problem. The first advantage is that the methodology is described at a symbolic level and, thus, there are many ways to implement the method. Second, a geometric implementation of this methodology (ND method) has been demonstrated to address difficult navigation cases, which translate in to achieve safe navigation in dense, complex, and difficult scenarios.

Abstraction Construction

For these vehicles, the configuration space CS is three-dimensional. The idea is to construct, centered in the robot at each time t_i , the manifold of the configuration space $ARM(\mathbf{q}_{t_i}) \equiv ARM$ defined by elementary circular paths. The function that defines the manifold is

$$\theta = f(x, y) = \begin{cases} \arctan 2 \left(x, \frac{x^2 - y^2}{2y} \right) & \text{if } y \geq 0, \\ -\arctan 2 \left(x, -\frac{x^2 - y^2}{2y} \right) & \text{otherwise.} \end{cases} \quad (47.19)$$

It is easy to see that function f is differentiable in $\mathbb{R}^2 \setminus (0, 0)$. Thus $(x, y, f(x, y))$ defines a two-dimensional manifold in $\mathbb{R}^2 \times S^1$ when $(x, y) \in \mathbb{R}^2 \setminus (0, 0)$. This manifold ARM contains all the configurations that can be reached at each step of the obstacle avoidance.

Next, in the ARM one computes the exact region of the configurations in collision CO_{ARM} given any shape of the robot (i.e., obstacle representation in the manifold). Given an obstacle point (x_p, y_p) and a point of the robot bounds (x_r, y_r) , a point (x_s, y_s) of the CO_{ARM} boundary is obtained by

$$\begin{aligned} x_s &= (x_f + x_i) \cdot a, \\ y_s &= (y_f - y_i) \cdot a, \end{aligned} \quad (47.20)$$

with

$$\begin{aligned} a &= \left\{ [(y_f^2 - y_i^2) + (x_f^2 - x_i^2)] [(y_f - y_i)^2 + (x_f - x_i)^2] \right\} \\ &\quad \times \left[(y_f - y_i)^4 + 2(x_f^2 + x_i^2)(y_f - y_i)^2 \right. \\ &\quad \left. + (x_f^2 - x_i^2)^2 \right]^{-1}. \end{aligned}$$

This result is used to map the robot bounds for all obstacles in the manifold, computing the exact shape of the CO_{ARM} . Next, one computes the nonadmissible configurations CNA_{ARM} in the manifold ARM , which correspond to configurations that once reached at a given

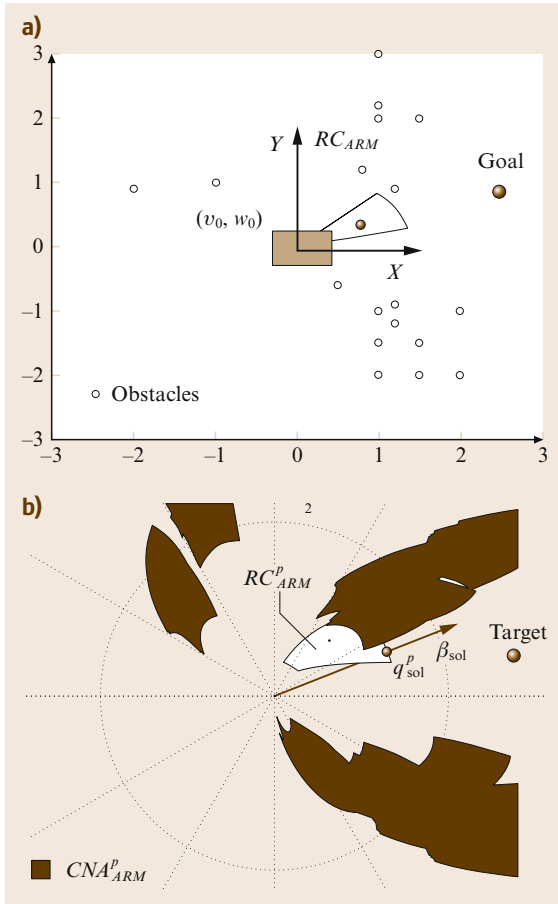

Fig. 47.15 (a) Robot location, obstacle information and goal location. (b) The abstraction layer in ARM^p . In this representation the obstacles are the nonadmissible region CNA_{ARM}^p in ARM and that the motion is omnidirectional (applicability conditions of many obstacle avoidance methods). The method is applied to obtain the most promising direction β_{sol} , used to obtain the configuration solution q_{sol}^p in the set of reachable configurations RC_{ARM}^p . Finally, the solution is the control u_{sol} that reaches this configuration at time T . This control complies with the kinematics and dynamics and takes into account the exact vehicle shape

velocity in time T , the vehicle cannot be stopped by applying the maximum deceleration without collision (i. e., there is not enough braking distance). These regions CNA_{ARM} are the CO_{ARM} enlarged by a magnitude that depends on the maximum vehicle accelerations. The set of configurations RC_{ARM} reachable by controls in a short period of time \mathcal{U}_A is also computed in the ARM . Finally, a change of coordinates is applied to ARM leading to ARM^p . Its effect is that the elementary circular paths become straight segments in the manifold. As a consequence, the problem now is to move an

omnidirectional point in a bidimensional space free of any constraint.

Method Application

The final step is to apply the avoidance method on the ARM^p to avoid the CNA_{ARM}^p regions. The method solution β_{sol} is the most promising direction in ARM^p . This direction is used to select an admissible location $q_{sol}^p \notin CNA_{ARM}^p$ in the set of dynamic reachable configurations RC_{ARM}^p . Finally, the control u_{sol} that leads to this location at time T is selected. By construction, this control is kinematically and dynamically admissible, avoids collisions with the exact vehicle shape, and takes into account the braking distance (Fig. 47.15).

Note how with these techniques, the three-dimensional obstacle avoidance problem is converted into the simple problem of moving a point in a two-dimensional space without kinematic and dynamic restrictions (applicability conditions of many existing methods). Thus, many existing methods can be applied in this abstraction, and as a consequence, the solutions take the vehicle constraints into account.

47.10.2 Techniques of Decomposition in Subproblems

These techniques address the obstacle avoidance problem taking into account the vehicle constraints by breaking down this problem into subproblems:

1. Obstacle avoidance
2. Kinematics and dynamics
3. The shape.

Each subproblem is dealt with in sequence (Fig. 47.16).

Obstacle Avoidance

First the obstacle avoidance method is used by assuming a circular and omnidirectional vehicle. The solution is the most promising motion direction and the velocity $u_1 = (v_1, \theta_1)$ to direct the vehicle towards the target.

Kinematics and Dynamics

Second, this control is converted into a control that complies with the kinematics and dynamics, which tends to align the vehicle with the instantaneous motion direction θ_1 of u_1 . For example, [47.60, 61] modify the output of the obstacle avoidance method by a feedback action that aligns the vehicle with the direction solution in a least squares fashion. Moreover, [47.59] use a dynamic controller of the vehicle. This controller models the behavior of the vehicle as it would be pulled by a virtual force, and computes the mo-

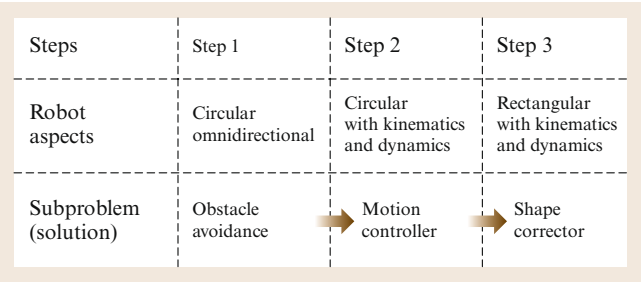

Fig. 47.16 Decomposition of the obstacle avoidance problem into subproblems that are addressed in steps, successively incorporating the vehicle aspects

tion that would result after applying this force during a short period of time. The motion generated is the

new control. In order to use the controller, the previous control u_1 is converted into an instantaneous force $F = (\theta_1, F_{\max}(v_1/v_{\max}))$ input of the controller, which computes a control u_2 that complies with the kinematic and dynamics.

Shape

The final step is to assure that the control u_2 obtained in the previous step avoids collisions with the exact shape of the vehicle. To do this, a shape corrector is used to check collisions by dynamic simulation of the control. If there is collision, there is a search in the set of reachable controls (47.14) until one of them is collision free. The result of this process is a motion control u_i that guarantees obstacle avoidance and complies with the kinematics and dynamics of the vehicle.

47.11 Integration Planning – Reaction

In this section we show how the obstacle avoidance methods are integrated in real systems. On the one hand, the obstacle avoidance methods are local techniques to address the motion problem. Thus, they are doomed to fall in local minima that translate in trap situations or cyclic motions. This reveals the necessity of a more global reasoning. On the other hand, motion planning techniques compute a geometric path free of collisions, which guarantees global convergence. However, when the scenarios are unknown and evolve, these techniques fail, since the precomputed paths will almost surely collide with obstacles. It seems clear that one key aspect to build a motion system is to combine the best of both worlds: the global knowledge given by motion planning and the reactivity of the obstacle avoidance methods.

The most extended ways to specify the interaction between the deliberation and reaction are: (i) to precompute a path to the target deformed in execution as a function of the changes in the scenario obtained from the sensor information (systems of path deformation), for example, [47.62–67]. (ii) To use a planner at a high frequency with a tactical role, leaving the degree of execution to the reactor [47.68–73].

47.11.1 Systems of Path Deformation

Elastic bands is a method that initially assumes the existence of a geometric path to the target location (computed by a planner). The path is assimilated with a band, subjected to two types of forces: an inner contraction force and an external force. The inner force simulates the tension of a strip and maintains the stress. The external force is exerted by the obstacles and moves the band far from them. During the execution, the new

obstacles produce forces that remove the band far from them, guaranteeing their avoidance. These methods are described in Chap. 37.

An extension of the method of path deformation was proposed in [47.64] for nonholonomic systems (VIDEO 80). Even though the objective is the same as for mobile robots without kinematic constraints, avoiding obstacle while following a trajectory, the concepts are completely different. The trajectory Γ of a nonholonomic system is completely defined by an initial configuration $\Gamma(0)$ and the value of the input function $u \in C^1(I, \mathbb{R}^m)$, where I is an interval. The trajectory deformation method for nonholonomic systems is thus based on the perturbation of the input function of the current trajectory in order to achieve three objectives:

- 1. Keeping the nonholonomic constraints satisfied
- 2. Getting away from obstacles detected online by on-board sensors
- 3. Keeping unchanged the initial and last configurations of the trajectory after deformation.

Perturbing the input function of Γ , by a vector-valued input perturbation $v \in C^1(I, \mathbb{R}^m)$, yields a trajectory deformation $\eta \in C^1(I, \mathbb{R}^n)$

$$u \leftarrow u + \tau v \Rightarrow \Gamma \leftarrow \Gamma + \tau \eta,$$

where τ is a positive, asymptotically small real number. As an approximation of order 1, the relation between u and η is given by the linearized system, which we do not express here.

Potential Field of Obstacles

Obstacles are taken into account by defining a potential field over the configuration space, which increases when

the robot gets closer to obstacles. This potential field is lifted into the space of trajectories by integration along the trajectory of the configuration potential value.

Discretization of the Input Space

The space $C^1(I, \mathbb{R}^m)$ of input perturbations is an infinite-dimensional vector space. The choice of an input perturbation is restricted to a finite-dimensional subspace spanned by p arbitrary test functions, e_1, \dots, e_p where p is a positive integer. An input perturbation: $u = \sum_{i=1}^p \lambda_i e_i$ is thus defined by a vector $\lambda \in \mathbb{R}^p$. The variation of the trajectory potential is linear with respect to λ .

Boundary Conditions

The boundary conditions consisting in applying a trajectory perturbation equal to zero at both ends of interval I is linear with respect to λ . It is, therefore, easy to find a vector λ making the potential decrease and satisfying the boundary conditions.

Nonholonomic Constraint Deviation

The approximation of order 1 in the relation between the input perturbation and trajectory deformation induces a side effect: after a few iterations, the nonholonomic constraints are no longer satisfied. This side effect is corrected by considering an augmented system with n control vector fields f_1, \dots, f_n spanning \mathbb{R}^n for each configuration and by keeping the input components u_{m+1} to u_n along the additional vector fields as close as possible to 0. Figure 47.17 shows an example of the trajectory deformation algorithm applied to a nonholonomic system.

47.11.2 Systems of Tactical Planning

The systems of tactical planning recompute at a high frequency a path to the target location, and use the main course to advise the obstacle avoidance module. The design of these motion systems involves at least the synthesis of three functionalities. The construction of a model, the deliberative planning, and the obstacle avoidance. The modeler constructs a representation base for deliberation and memory for the reactive behavior. The planner generates global plans used tactically to guide the obstacle avoidance module, which generates the local motion. Next we give a perspective of the three functionalities and three possible tools to implement them [47.73].

Model Builder Module

Construction of a model of the environment (to increase the spatial domain of the planning and used as local

Fig. 47.17 A differentially-driven mobile robot towing a trailer applying the trajectory deformation algorithm to avoid obstacles detected online

memory for obstacle avoidance). One possibility is to use a binary occupancy grid that is updated whenever a new sensory measurement is available, and to employ a scan matching technique [47.74, 75] to improve the vehicle odometry before integrating any new measure in the grid.

Planner Module

Extraction of the connectivity of the free space (used to avoid the cyclical motions and trap situations). A good choice is a dynamic navigation function such as the D^* [47.76, 77]. The idea behind the planner is to focus the search locally in the areas where the changes in the scenario structure have occurred and affect the computation of the path. The planner avoids the local minima and is computationally very efficient for real-time implementations.

Obstacle Avoidance Module

Computation of the collision-free motion. Any of the methods described in this chapter could be used. One possibility is the ND method (Sect. 47.9.6), since it has been demonstrated to be very effi-

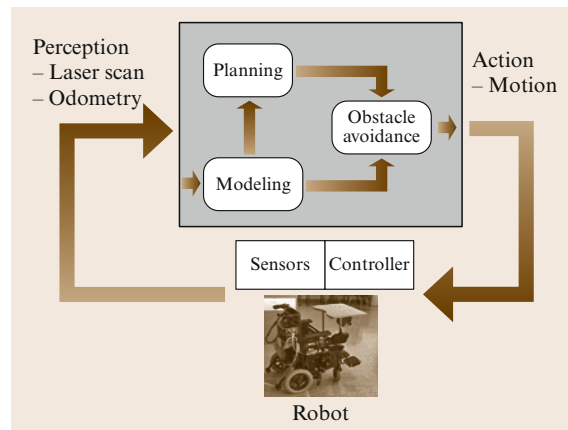

Fig. 47.18 Overview of the system of motion

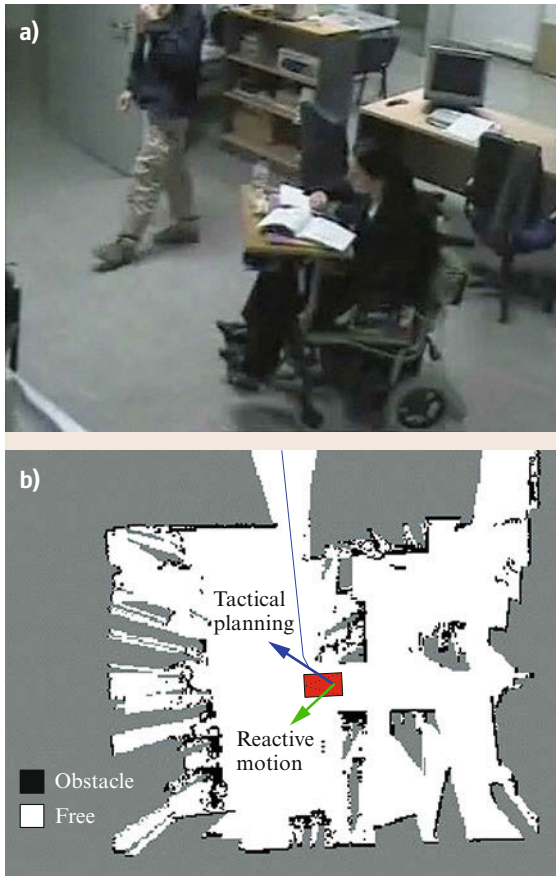

Fig. 47.19 (a) Snapshot of an experiment carried out with the motion system described working on a wheelchair robot equipped with a planar range laser sensor. (b) Information of the motion system at a given time: current accumulated map of the scenario, path computed with the planner and tactical direction of motion, and solution of the reactive obstacle avoidance method ◀

cient and robust in environments with little space to manoeuvre.

Globally the system works as follows (Fig. 47.18): given a laser scan and the odometry of the vehicle, the model builder incorporates this information into the existing model. Next, the information of the changes in obstacle and free space in the model is used by the planner module to compute the course to follow to reach the goal. Finally, the avoidance module uses the information of the obstacles contained in the grid and information of this tactical planner to generate the motion (to drive the vehicle free of collisions towards the goal). The motion is executed by the vehicle controller and the process restarts with a new sensorial measurement. It is important to stress that the three modules should work synchronously within the perception – action cycle for consistency reasons. The advantage of these systems is that the synergy of the modules allows to avoid trap situations and the cyclic motions (limitations associated to the local nature of the avoidance methods). Figure 47.19 shows a snapshot of an experiment carried out with this motion system.

47.12 Conclusions, Future Directions, and Further Reading

The algorithmic tools presented in this chapter show that motion planning and obstacle avoidance research techniques have reached a level of maturity that allow their transfer onto real platforms (👁 VIDEO 710, 👁 VIDEO 714). Today, several indoor mobile robots use obstacle avoidance techniques on a daily basis to guide visitors in museums. Outdoor applications still require some developments in perception and modeling. For these applications, 3-D sensing capabilities are necessary to model the environment but also to detect obstacles. As an example, several car manufacturer are working on parallel parking assistance. The difficult point of this application is to build a model of a parking spot from 3-D data in a great variety of environments.

The main challenge of autonomous motion in mobile robots currently consists in integrating techniques from different robotics research domains in order to

plan and execute motions for very complex systems, like humanoid robots, for instance. Integration in the sense that different software components need to work together on a machine but also in a scientific meaning: the classical motion planning formulation with configuration variables that locate the robot with respect to a global reference frame does not fit partially known environments with imprecise maps. Robotic tasks like motion need to be specified with respect to landmarks of the environment. For instance, grasping an object is by definition a motion specified with respect to the position of the object. Very little has been done to design a general framework in this direction.

For useful complementary reading on motion planning and obstacle avoidance for mobile robots see [47.5, 78–80].

48. Modeling and Control of Legged Robots

Pierre-Brice Wieber, Russ Tedrake, Scott Kuindersma

The promise of legged robots over wheeled robots is to provide improved mobility over rough terrain. Unfortunately, this promise comes at the cost of a significant increase in complexity. We now have a good understanding of how to make legged robots walk and run dynamically, but further research is still necessary to make them walk and run efficiently in terms of energy, speed, reactivity, versatility, and robustness. In this chapter, we will discuss how legged robots are usually modeled, how their stability analysis is approached, how dynamic motions are generated and controlled, and finally summarize the current trends in trying to improve their performance. The main problem is avoiding to fall. This can prove difficult since legged robots have to rely entirely on available contact forces to do so. The temporality of leg motions appears to be a key aspect in this respect, as current control solutions include continuous anticipation of future motion (using some form of model predictive control), or focusing more specifically on limit cycles and orbital stability.

The promise of legged robots over standard wheeled robots is to provide improved mobility over rough terrain. This promise builds on the decoupling between the environment and the main body of the robot that the presence of articulated legs allows, with two consequences. First, the motion of the main body of the robot

can be made largely independent from the roughness of the terrain, within the kinematic limits of the legs: legs provide an active suspension system. Indeed, one of the most advanced hexapod robots of the 1980s was aptly called the Adaptive Suspension Vehicle [48.1]. Second, this decoupling allows legs to temporarily leave their

contact with the ground: isolated footholds on a discontinuous terrain can be overcome, allowing to visit places absolutely out of reach otherwise. Note that having feet firmly planted on the ground is not mandatory here: skating is an equally interesting option, although rarely approached so far in robotics.

Unfortunately, this promise comes at the cost of a hindering increase in complexity. It is only with the unveiling of the Honda P2 humanoid robot in 1996 [48.2],

and later of the Boston Dynamics BigDog quadruped robot in 2005 that legged robots finally began to deliver real-life capabilities that are just beginning to match the long sought animal-like mobility over rough terrain. Not matching yet the capabilities of humans and animals, legged robots do contribute however already to understanding their locomotion, as evidenced by the many fruitful collaborations between robotics and biomechanics researchers.

48.1 A Brief History of Legged Robots

Before the advent of digital computers, legged machines could be approached only by electromechanical means, lacking in advanced feedback control. This *pre-robotics* period culminated with the General Electric Walking Truck developed by Ralph Mosher, which inspired awe in the mid 1960s. The limb motions of this elephant-size quadruped machine were directly reflecting the limb motions of the onboard operator, who was responsible for all motion control and synchronization. Unfortunately, the strenuous concentration that this required limited operation to less than 15 minutes.

Digitally controlled legged robots started to appear in the late 1960s. Among early pioneers, Robert McGhee initiated a series of quadruped and hexapod robots first at University of South California, then at Ohio State University, culminating in the mid 1980s with the Adaptive Suspension Vehicle, a human carrying hexapod vehicle walking on natural and irregular outdoor terrain [48.1], while Ichiro Kato initiated a long series of biped and humanoid robots in the Waseda University, a series still continuing nearly half a century later [48.3]. But by the end of the 1970s, all legged robots were still limited to quasi-static gaits, i. e., slow walking motions with the center of mass of the robot always kept above its feet.

The transition to dynamic legged locomotion occurred in the beginning of the 1980s, with the first dynamically walking bipedal robot demonstrated at the Tokyo University [48.4], and the famous series of hopping and running monopodal, bipedal and quadrupedal robots developed at the MIT (Massachusetts Institute of Technology) LegLab under the direction of *Marc Raibert* [48.5]. Key theoretical breakthroughs came in the end of the 1980s, when *Tad McGeer* demonstrated that stable dynamic walking motions could be obtained by

pure mechanical means, giving rise to a whole new field of research, *passive dynamic walking*, introducing new, key concepts such as orbital stability using Poincaré maps [48.6], with one simple conclusion: you need not have complete (or any) control to be able to walk dynamically and efficiently.

Legged robots were still mostly research laboratory curiosities working in limited situations when Honda unveiled the P2 humanoid robot in 1996 [48.2], a decade long secret project demonstrating unprecedented versatility and robustness, followed in 2000 by the Asimo humanoid robot. The world of humanoid and legged robots was ripe for companies to begin investing. A handful of other Japanese companies such as Toyota or Kawada were quick to follow with their own humanoid robots, while Sony began selling more than 150 000 of its Aibo home companion robot dogs. Boston Dynamics, a company *Marc Raibert* founded after leaving the MIT LegLab, finally unveiled its BigDog quadruped robot in 2005 [48.7], which was the first to demonstrate true animal-like locomotion capabilities on rough terrain.

The progress over the last decades has been remarkable. Profound questions have finally been answered: we now understand how to make legged robots walk and run dynamically. But other profound questions still have to be answered, such as how best to make them walk and run *efficiently*. The performance of legged robots needs to be improved in many ways: energy, speed, reactivity, versatility, robustness, etc. We will therefore discuss in this chapter how legged robots are usually modeled in Sect. 48.2 and how dynamic motions are currently generated and controlled in Sections 48.4 and 48.5, before discussing in Sect. 48.6 the current trends in improving their efficiency.

48.2 The Dynamics of Legged Locomotion

One of the major difficulties in making a legged robot walk or run is keeping its balance: where should the

robot place its feet, how should it move its body in order to move safely in a given direction, even in case

of strong perturbations? This difficulty comes from the fact that contact forces with the environment are an absolute necessity to generate and control locomotion, but they are limited by the mechanical laws of unilateral contact.

This essential role of the contact forces is particularly clear in the derivatives of the total linear and angular momenta of the robot, the former involving the motion of its center of mass. Because of the importance of contact forces for legged locomotion, we briefly discuss here their different models.

48.2.1 Lagrangian Dynamics

Structure of the Configuration Space

As for every robot moving in their 3-D environment (in space or underwater for example), the configuration space of legged robots combines the configuration $\hat{q} \in \mathbb{R}^N$ of their N joints with a global position $\mathbf{x}_0 \in \mathbb{R}^3$ and orientation $\boldsymbol{\theta}_0 \in \mathbb{R}^3$ (representing an element of $SO(3)$)

$$\mathbf{q} = \begin{pmatrix} \hat{q} \\ \mathbf{x}_0 \\ \boldsymbol{\theta}_0 \end{pmatrix}. \quad (48.1)$$

The position \mathbf{x}_0 and orientation $\boldsymbol{\theta}_0$ are typically those of a central body (pelvis or trunk) or of an extremity (foot or hand).

Structure of the Lagrangian Dynamics

The specific structure of the configuration space outlined above is naturally reflected in the Lagrangian dynamics

$$\begin{aligned} \mathbf{M}(\mathbf{q}) \left[\begin{pmatrix} \ddot{\hat{q}} \\ \ddot{\mathbf{x}}_0 \\ \ddot{\boldsymbol{\theta}}_0 \end{pmatrix} + \begin{pmatrix} \mathbf{0} \\ \mathbf{g} \\ \mathbf{0} \end{pmatrix} \right] + \mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}) \\ = \begin{pmatrix} \mathbf{u} \\ \mathbf{0} \\ \mathbf{0} \end{pmatrix} + \sum_i \mathbf{C}_i(\mathbf{q})^T \mathbf{f}_i \end{aligned} \quad (48.2)$$

of the system, where $\mathbf{M}(\mathbf{q}) \in \mathbb{R}^{(N+6) \times (N+6)}$ is the generalized inertia matrix of the robot, $-\mathbf{g} \in \mathbb{R}^3$ is the constant gravity acceleration vector, $\mathbf{n}(\mathbf{q}, \dot{\mathbf{q}}) \in \mathbb{R}^{N+6}$ is the vector of Coriolis and centrifugal effects, $\mathbf{u} \in \mathbb{R}^N$ is the vector of joint torques, and for all i , $\mathbf{f}_i \in \mathbb{R}^3$ is a force exerted by the environment on the robot and $\mathbf{C}_i(\mathbf{q}) \in \mathbb{R}^{(N+6) \times 3}$ is the associated Jacobian matrix [48.8].

Since the vector \mathbf{u} of joint torques has the same size as the vector \hat{q} of joint positions, the whole dynamics including the global position \mathbf{x}_0 and orientation $\boldsymbol{\theta}_0$ appears to be underactuated if no external forces \mathbf{f}_i are exerted.

48.2.2 Newton and Euler Equations of Motion

Center of Mass and Angular Momentum

A consequence of the structure (48.2) of the Lagrangian dynamics is that the part of this dynamics which is not directly actuated involves the Newton and Euler equations of motion of the robot taken as a whole ([48.8] for detailed derivations). The Newton equation can be written in the following way

$$m(\ddot{\mathbf{c}} + \mathbf{g}) = \sum_i \mathbf{f}_i, \quad (48.3)$$

with m the total mass of the robot and \mathbf{c} the position of its center of mass (COM). The Euler equation can be expressed with respect to the COM in the following way

$$\dot{\mathbf{L}} = \sum_i (\mathbf{p}_i - \mathbf{c}) \times \mathbf{f}_i, \quad (48.4)$$

with \mathbf{p}_i the points of applications of the forces \mathbf{f}_i and

$$\mathbf{L} = \sum_k (\mathbf{x}_k - \mathbf{c}) \times m_k \dot{\mathbf{x}}_k + \mathbf{I}_k \boldsymbol{\omega}_k \quad (48.5)$$

the angular momentum of the whole robot with respect to its COM, with $\dot{\mathbf{x}}_k$ and $\boldsymbol{\omega}_k$ the translation and rotation velocities of the different parts k of the robot, m_k and \mathbf{I}_k their masses and inertia tensor matrices (expressed in global coordinates).

The Newton equation makes it obvious that the robot needs external forces \mathbf{f}_i in order to move its COM in a direction other than that of gravity. The Euler equation is more subtle, as we will see during flight phases.

Flight Phases

During flight phases, when a legged robot is not in contact with its environment, not experiencing any contact forces \mathbf{f}_i , the Newton equation (48.3) simplifies to

$$\ddot{\mathbf{c}} = -\mathbf{g}. \quad (48.6)$$

In this case, the COM invariably accelerates along the gravity vector $-\mathbf{g}$ with constant horizontal speed, following a standard falling motion: there is absolutely no possibility to control the COM to move in any different way. The Euler equation (48.4) simplifies in the same way to

$$\dot{\mathbf{L}} = 0, \quad (48.7)$$

imposing a conservation of the angular momentum \mathbf{L} . In this case, however, the robot is still able to generate and control both joint motions and global rotations, this is how cats are able to fall back on their feet when

Fig. 48.1 Even though the angular momentum is constant during flight phases, the robot is still able to generate and control rotations of the whole body with the help of leg or arm motions (light brown), as a result of the *nonholonomy* of the angular momentum. This is how cats fall back on their feet when dropped from any initial orientation

dropped from any initial orientation (Fig. 48.1). This is a result of the *nonholonomy* of the angular momentum (48.5) which is not the derivative of any function of the configuration of the robot [48.9]. As a result, even though the angular momentum \mathbf{L} is kept constant during the whole flight phase, the joint configuration $\hat{\mathbf{q}}$, and the global orientation θ_0 of the robot can be driven to any desired value at the end of the flight phase. We will see in Sect. 48.5 how this impacts the control of legged robots. Note that the dynamics of legged robots during flight phases is similar to the dynamics of free-floating space robots discussed in Chap. 55. Further discussion and developments can be found there.

In Contact with a Flat Ground: The Center of Pressure

In case the forces applied by the environment on the robot are due to contacts with a flat ground (while standing still, walking or running), let us consider a reference frame oriented along the ground, with the z axis orthogonal to it (therefore tilted if the ground is tilted, see Fig. 48.5). Without loss of generality, let us suppose that the points of contact, \mathbf{p}_i , with the ground are all such that $p_i^z = 0$.

Let us consider then the sum of the Euler (48.4) and the cross product of the COM \mathbf{c} with the Newton (48.3)

$$m\mathbf{c} \times (\ddot{\mathbf{c}} + \mathbf{g}) + \dot{\mathbf{L}} = \sum_i \mathbf{p}_i \times \mathbf{f}_i, \quad (48.8)$$

and let us divide the result by the z coordinate of the Newton equation to obtain

$$\frac{m\mathbf{c} \times (\ddot{\mathbf{c}} + \mathbf{g}) + \dot{\mathbf{L}}}{m(\ddot{c}^z + g^z)} = \frac{\sum_i \mathbf{p}_i \times \mathbf{f}_i}{\sum_i f_i^z}. \quad (48.9)$$

Since $p_o^z = 0$, the x and y coordinates of this equation can be simplified in the following way

$$\begin{aligned} \mathbf{c}^{x,y} - \frac{c^z}{\ddot{c}^z + g^z} (\ddot{\mathbf{c}}^{x,y} + \mathbf{g}^{x,y}) + \frac{1}{m(\ddot{c}^z + g^z)} \mathbf{S} \dot{\mathbf{L}}^{x,y} \\ = \frac{\sum_i f_i^z \mathbf{p}_i^{x,y}}{\sum_i f_i^z}, \end{aligned} \quad (48.10)$$

with a simple rotation matrix

$$\mathbf{S} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}.$$

On the right hand side of (48.10) appears the definition of the center of pressure (COP) \mathbf{z} of the contact forces, \mathbf{f}_i . These contact forces are usually unilateral (the robot can push on the ground, not pull)

$$f_i^z \geq 0, \quad (48.11)$$

which implies that the CoP is bound to lie in the convex hull of the contact points (Fig. 48.2)

$$\mathbf{z}^{x,y} = \frac{\sum_i f_i^z \mathbf{p}_i^{x,y}}{\sum_i f_i^z} \in \text{conv} \{ \mathbf{p}_i^{x,y} \}. \quad (48.12)$$

Combining this inclusion with the dynamic (48.10) reveals an ordinary differential inclusion (ODI)

$$\begin{aligned} \mathbf{c}^{x,y} - \frac{c^z}{\ddot{c}^z + g^z} (\ddot{\mathbf{c}}^{x,y} + \mathbf{g}^{x,y}) + \frac{1}{m(\ddot{c}^z + g^z)} \mathbf{S} \dot{\mathbf{L}}^{x,y} \\ = \mathbf{z}^{x,y} \in \text{conv} \{ \mathbf{p}_i^{x,y} \}, \end{aligned} \quad (48.13)$$

Fig. 48.2 The CoP \mathbf{z} is bound to lie in the convex hull of contact points \mathbf{p}_i

Compliant Contact Models

Compliant contact models take into account the visco-elastic properties of the materials in contact in the direction orthogonal to the contact surfaces

$$f_i^z = -K_i p_i^z - \Lambda_i \dot{p}_i^z \text{ if } p_i^z \leq 0, \quad (48.18)$$

where K_i and Λ_i are stiffness and damping coefficients, respectively. In this case, the normal force f_i^z appears to be the result of a penetration of the contact point below the contact surface, i. e., when $p_i^z < 0$. Note that, as it is here, this model doesn't satisfy the unilaterality condition (48.11) in all situations and needs therefore to be saturated to enforce this property. Of course, when there is no contact, there is no contact force

$$f_i^z = 0 \text{ if } p_i^z > 0. \quad (48.19)$$

A similar spring-damper model can also be used to determine the frictional contact force $f_i^{x,y}$, subject to the bounds of the friction cone (48.17).

Rigid Contact Models

Rigid contact models are somewhat simpler to introduce: either there is contact and the normal force can take any nonnegative value,

$$f_i^z \geq 0 \text{ if } p_i^z = 0, \quad (48.20)$$

or there is no contact and no contact force

$$f_i^z = 0 \text{ if } p_i^z > 0. \quad (48.21)$$

In this case, no penetration of the contact points below the contact surfaces are considered. Note also that the unilaterality condition (48.11) is satisfied here by definition. As a matter of fact, this rigid model can be summarized in the following way

$$f_i^z \geq 0, p_i^z \geq 0, f_i^z p_i^z = 0, \quad (48.22)$$

where it appears that both the normal force f_i^z and the position of the contact point with respect to the contact surface p_i^z must be nonnegative, but at least one of them must be equal to 0. This is called a *complementarity condition*. Analogous to (48.20) and (48.21), it defines the normal force to be either zero, or the force necessary to maintain $p_i^z = 0$. Note that the sticking-or-sliding behavior of Coulomb friction can also be represented with such a complementarity condition. Note also that this set of implicit equations may not have a solution or may have multiple ones in certain pathologic situations [48.25].

Rigid and compliant contact models are compared in Fig. 48.4 in a static situation (when $\dot{p}_i^z = 0$), showing

Fig. 48.4 Comparison of a rigid (blue) and compliant (red) contact model in a static situation. Unlike the rigid model, the compliant model considers a penetration of the contact point below the contact surface, when $p_i^z < 0$. The graph of the rigid model, with the specific shape of a right angle, is called a Signorini graph

clearly how the rigid model corresponds to an infinitely stiff compliant model. Compliant contact models can model more accurately the deformation of the contacting bodies, but accurate models often require very stiff springs, causing the resulting differential equations to be numerically stiff, what can slow down or complicate numerical analysis. Rigid models are comparatively more straightforward to integrate and analyze, with purely rigid bodies and contact surfaces. They are therefore preferred when theoretically or numerically studying the stability of legged robots, when optimizing walking or running trajectories, etc.

Impacts

Since rigid contact models do not allow penetration of the contact points below the contact surfaces, when a point p_i reaches a contact surface $p_i^z = 0$ with a velocity $\dot{p}_i^z < 0$, this velocity has to change instantaneously in order to satisfy the no-penetration assumption, $p_i^z \geq 0$ [48.26]. What happens in this situation is an *impact*, a discontinuity of the velocity, where we need to distinguish the velocity of the robot before impact \dot{q}^- , and its velocity after impact, \dot{q}^+ . A straightforward integration of the Lagrangian dynamics (48.2) over a time singleton [48.27] gives us a relation between pre- and post-impact velocities and impulsive forces F_i

$$M(q) (\dot{q}^+ - \dot{q}^-) = \sum_i C_i(q)^T F_i. \quad (48.23)$$

But in order to completely define the impact law and compute the post-impact velocity, we also need a model of the impulsive forces. Unfortunately, this is a complex problem still open to research [48.28, 29], especially in situations of multiple contacts which are the standard situation for legged robots. The usual approach for

legged robots is therefore to assume the post-impact behavior, usually considering that the contact points eventually stick to the contact surfaces

$$\dot{p}_i^+ = C_i \dot{q}^+ = 0. \quad (48.24)$$

This is, however, a strong assumption, and reality can be much more complex, as demonstrated in [48.30]. Moreover, a recent study shows that post-impact sticking may not always be desirable [48.31].

Impacts are central in most stability analyses of passive dynamic walking machines (Sect. 48.6), but they can be potentially destructive for the mechanical parts of a robot. As a result, they are often carefully avoided and therefore generally disregarded outside of passive dynamic walkers. A recent study shows however that this is probably a mistake [48.32].

Hybrid and Nonsmooth Dynamics

With rigid contacts, the dynamics of legged robots appears to switch, depending on the contact situations (48.20) or (48.21). Discontinuities of the state of the robot also occur at impacts. A classical way to combine these different aspects is with a hybrid dynamical system. This approach has however some limitations [48.33, 34], the most obvious one being its incapacity to handle properly *Zeno behaviors*, infinite accumulations of impacts in finite time [48.35]. An example of such a situation is when a legged robot is

rigidly standing on one foot, and gently rocking from one contact edge to the opposite contact edge, with a continuously decreasing period (at least according to the perfectly rigid model).

Impacts with multiple contacts and Zeno behaviors are not the only difficulties with rigid contact models: there is also the Painlevé paradox, tangential impacts, impacts without collisions, etc. The nonsmooth dynamics approach [48.25, 27, 33, 34], where the Lagrangian dynamics is turned into a measure differential equation, accelerations being abstract measures, velocities being functions with locally bounded variations, appears to be a much more adequate way to deal with all these intricacies. But it has not been widely adopted for legged robots because of a significant increase in mathematical complexity.

Many of the complexities of rigid body contact dynamics can be avoided by discretizing the system dynamics in time and reasoning about the integral of contact forces acting over a time step. In particular, no distinction is made between impulses and finite contact forces over a time step. By conservatively approximating the friction cone as a polyhedron, forward dynamics can be cast as a linear complementarity problem (LCP) [48.36], for which efficient solvers exist. This has become a popular formulation for simulation of rigid bodies in frictional contact and it has recently seen applications to control design for legged systems [48.37].

48.3 Stability Analysis – Not Falling Down

The robot model described above represents a complex, constrained, nonlinear dynamical system. Our goal for this section is to understand the long-term behavior of this dynamical system, to answer questions like, *Will the robot fall down?* As we will see in the following sections, this long-term behavior can be changed by open-loop or closed-loop feedback control, with the explicit goal of minimizing the likelihood that the robot will fall down.

For controlled nonlinear dynamical systems, there are a number of useful concepts relating to their safety and stability, including:

- **Fixed points:** Stable fixed points represent the static postures in which the robot can safely stand still.
- **Limit cycles:** Limit cycles provide a natural extension of fixed-point analysis to *periodic* walking or running motions.
- **Viability:** Viability is a concept of controlled invariance, which analyzes the set of states from which

the robot is able to avoid to fall. Unfortunately, this property can be intractable to compute.

- **Controllability:** Controllability provides a slightly restricted notion of viability, analyzing the set of states from which the robot is capable of returning to a particular fixed point (or limit cycle). This can be more tractable to compute than viability, especially for simple models.

In addition, if there are unknown errors in the robot model, if there is uncertainty about the environment (e.g., the location of the ground), or if there are unmodeled disturbances, then additional tools are available from robustness analysis and stochastic stability:

- **Robust stability:** Robust stability (or viability) examines the properties of the system considering worst-case (bounded) disturbances. For instance, a robust controller may be able to guarantee that a fixed point is stable even if the estimate of the mass of the trunk is wrong by $\pm 10\%$.

- *Stochastic stability*: Stochastic analysis provides tools to investigate the *probability* of falling down. For many robot disturbance models, the system will always fall eventually (with probability one), but analysis can reveal long-living *metastable* distributions.
- *Input-output stability*: This analysis treats a particular disturbance as an input, a performance criteria as output, and attempts to compute a relative *gain* or *sensitivity* of the robot performance due to this input.
- *Stability margins*: Robustness analysis can be difficult. In practice control designers often settle for the system staying comfortably away from the boundaries of deterministic stability.

We give a very brief overview of these tools in the remainder of this section, with an attempt to emphasize features of the analysis that are particular to legged robots.

48.3.1 Fixed Points

Given a first-order ordinary differential equation governed by $\dot{\mathbf{x}} = \mathbf{a}(\mathbf{x})$, a *fixed point* of the system is a state \mathbf{x}^* , for which $\mathbf{a}(\mathbf{x}^*) = 0$. The governing equations for a legged robot, given in Sect. 48.2, are second-order, take a control input, and potentially require a differential inclusion to describe the contact forces, but the notion of a fixed point is still meaningful. Here a fixed point is a configuration \mathbf{q}^* , for which there exists feasible control inputs \mathbf{u}^* , and feasible contact forces \mathbf{f}^* , so that $\dot{\mathbf{q}}^* = \ddot{\mathbf{q}}^* = \mathbf{0}$ is a solution to (48.2). A fixed point of this system is a posture in which the legged robot is able to stand still.

In static situations, when $\ddot{\mathbf{c}} = \dot{\mathbf{L}} = \mathbf{0}$, the ODI (48.13) gives the following necessary condition

$$\mathbf{c}^{x,y} - \frac{c^z}{g^z} \mathbf{g}^{x,y} = \mathbf{z}^{x,y} \in \text{conv} \{ \mathbf{p}_i^{x,y} \} \quad (48.25)$$

for a static equilibrium on a flat ground. This necessary condition states that the COM \mathbf{c} must project on the ground along the gravity vector $-\mathbf{g}$, inside the convex hull of the contact points \mathbf{p}_i , also known as the *support polygon* (Fig. 48.5). This is a very well known and widely used necessary condition. Note, however, that it is valid only when considering contacts with a flat ground [48.15].

Once a fixed point has been found, one would often like to examine its stability. For smooth nonlinear differential equations, local stability can often be established via linearizing the dynamics at the fixed point and then applying well-known tools from linear systems theory. Indeed, these tools can also be applied

Fig. 48.5 A necessary static equilibrium condition on a flat ground is that the COM \mathbf{c} must project on the ground along the gravity vector $-\mathbf{g}$ inside the convex hull of the contact points \mathbf{p}_i also known as the *support polygon* (red)

here, under the strong assumption that the contact conditions do not change (e.g., either $f_i^z = 0$ and $p_i^z \geq 0$, or $f_i^z \geq 0$ and $p_i^z = 0$). Each active contact adds an equality constraint to the linearized system and the eigenvalues of this constrained linear system are only meaningful in the minimal coordinates; e.g., for a robot standing on horizontal ground the assumption precludes the ability to examine a perturbation of the entire robot in the vertical direction. Note that in a hybrid model of the legged robot, this assumption is equivalent to linearizing within a single hybrid mode, and it is common practice to describe each hybrid mode in its minimal coordinates [48.38]. Once local stability is established, it may also be possible to understand the *region of attraction* of the fixed point [48.39, 40]. Evaluating the stability of these models through changes in contact configurations is a new and important area of research. For recent work, see for instance [48.41].

48.3.2 Limit Cycles

A natural extension of fixed-point analysis to walking and running motions is to examine the existence and stability of periodic orbits, or limit cycles, of the dynamical system. Here a periodic orbit is a solution $\{ \langle \mathbf{q}(t), \mathbf{u}(t), \mathbf{f}(t) \rangle \mid t \in [0, \infty) \}$ of the dynamical system with a finite period $T > 0$ such that $\mathbf{q}(t+T) = \mathbf{q}(t)$, $\mathbf{u}(t+T) = \mathbf{u}(t)$, and $\mathbf{f}(t+T) = \mathbf{f}(t)$. Almost always, periodic orbits are discovered numerically using techniques from motion planning like those described in Sect. 48.4. For passive, or very minimally actuated robots, the very existence of a periodic solution can be exciting [48.42]; robots with more actuators typically have an abundance of periodic solutions and planning techniques can be used to find solutions that, for instance, minimize the a quantity of interest such as the

cost of transport [48.43] or a measure of open-loop stability [48.44].

A periodic solution $\langle q_0(\cdot), u_0(\cdot), f_0(\cdot) \rangle$ with period T , is (asymptotically) *orbitally stable* [48.45] or *limit-cycle stable* if, given initial conditions $q(0)$ we have

$$\lim_{t \rightarrow \infty} \left[\min_{0 \leq t' < T} \|q(t) - q_0(t')\| \right] = 0. \quad (48.26)$$

The key feature here that there is no requirement that system trajectories converge in time; only the distance to the closest point on the orbit must go to zero. This stability can be defined for initial conditions restricted to a local neighborhood of $q_0(\cdot)$, for a region containing $q_0(\cdot)$, or globally (though no interesting legged robot is globally stable) and for inputs determined by a variety of open- or closed-loop control policies, $u(t) = \pi(t, q(t), \dot{q}(t), f(t))$. Under mild conditions, a sufficient criteria for establishing orbital stability is establishing fixed-point stability of a Poincaré map [48.46], as illustrated in Fig. 48.6. Due to the limitation that finding periodic solutions is typically done numerically, Poincaré map analysis is also typically done numerically, e.g., using finite differences to evaluate a local linearization of the map. This does not necessarily preclude rigorous analysis, and techniques exist to compute regions of attraction to hybrid limit cycles despite potential numerical inaccuracies [48.47]. Finally we note that limit cycle analysis can be applied (carefully) to solutions that are not periodic in all states – for instance, the x, y location of the floating base should be left out if the robot needs to make forward progress!

The primary advantage of limit cycle analysis is that, using the Poincaré map and related methods, many of the tools from fixed point analysis and linear systems theory can be easily extended to evaluate (local) stability and even to design a (locally) stabilizing controller. However, this is a very limited definition of locomotion; useful locomotion through nontrivial environments will likely require aperiodic motions.

Fig. 48.6 Illustration of a Poincaré surface \mathcal{P} defined on a periodic orbit (red) and a trajectory converging to the orbit (black)

Extensions to Aperiodic Stability

The notion of stability requires convergence to some nominal solution as time goes to infinity, thus the nominal solution must be defined over an infinite interval. A common approach involves stitching together periodic solutions with provably bounded finite-time transition maneuvers which can switch between them [48.48]. Orbital stability of an (infinite) aperiodic trajectory can be established using a transverse linearization or *moving Poincaré section* [48.49]. For real-world situations where the entire desired trajectory cannot be known apriori, these guarantees can also be provided using online motion planning and receding-horizon control [48.50].

48.3.3 Viability

If the objective of a legged robot is simply to avoid falling down, it can be possible then to directly define (at least theoretically) the set of postures $\mathcal{F} \subseteq \mathbb{R}^{N+6}$, where the robot has fallen down and that the robot should simply avoid. This leads to introducing the set of states from which the robot is able to avoid entering \mathcal{F} – the set of states from which the robot is able to avoid falling down. These states will be called *viable*, following the *viability* theory developed in [48.51] for general ODIs and introduced in the analysis of walking robots in [48.52]. In principle, the set of all viable states represents a safe operating envelope for the robot. It is typically intractable to compute explicitly but it can be approached indirectly in the case of walking robots in the following way.

Center of Mass Dynamics During Horizontal Walking

In case the robot is walking on a horizontal ground, the z axis is aligned with gravity, so $\mathbf{g}^{x,y} = 0$ and the ODI (48.13) becomes

$$\mathbf{c}^{x,y} - \frac{c^z}{\ddot{c}^z + g^z} \ddot{\mathbf{c}}^{x,y} + \frac{1}{m(\ddot{c}^z + g^z)} \mathbf{S} \dot{\mathbf{L}}^{x,y} \in \text{conv} \{ \mathbf{p}_i^{x,y} \}. \quad (48.27)$$

We can observe that it is linear with respect to the horizontal motion $\mathbf{c}^{x,y}$, $\ddot{\mathbf{c}}^{x,y}$ of the COM and variations of the angular momentum $\mathbf{L}^{x,y}$. The vertical motion c^z , \ddot{c}^z of the COM can usually be bounded, but in order to simplify the following derivations, let us suppose that the COM moves strictly horizontally above the ground, i. e., c^z is constant and $\ddot{c}^z = 0$, so the ODI becomes

$$\mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} + \frac{\mathbf{S} \dot{\mathbf{L}}^{x,y}}{m g^z} \in \text{conv} \{ \mathbf{p}_i^{x,y} \}. \quad (48.28)$$

Variations of the angular momentum \mathbf{L} can also be bounded in the x and y directions, but to make things

Fig. 48.7 A situation where, for some reason, no steps can be undertaken beyond a certain line (red), with \mathbf{a} a vector orthogonal to this line and pointing beyond it

as simple as possible, let us consider these variations to be equal to 0, so the ODI takes a very simple second order linear form

$$\mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} = \mathbf{z}^{x,y} \in \text{conv} \{ \mathbf{p}_i^{x,y} \}. \quad (48.29)$$

An Example of Inevitable Fall

Let us consider furthermore a situation where, for some reason (e.g., a cliff), no contact with the ground can be realized beyond a certain line (Fig. 48.7), with \mathbf{a} a vector orthogonal to this line and pointing beyond it. If the COM of the robot reaches this line at a time t_0 with a speed pointing beyond it ($\mathbf{a}^T \dot{\mathbf{c}}^{x,y}(t_0) > 0$), this linear ODI can be integrated analytically very simply and lead to the following inequality [48.53], valid at all time $t \geq t_0$

$$\mathbf{a}^T [\mathbf{c}^{x,y}(t) - \mathbf{c}^{x,y}(t_0)] \geq \frac{\mathbf{a}^T \dot{\mathbf{c}}^{x,y}(t_0)}{\omega} \sinh [\omega(t - t_0)], \quad (48.30)$$

with

$$\omega = \sqrt{\frac{g^z}{c^z}}. \quad (48.31)$$

The right hand side is increasing exponentially with time. As a result, the position $\mathbf{c}^{x,y}$ of the COM is diverging exponentially in the direction of the vector \mathbf{a} , leading inexorably to a fall.

A Sufficient Condition for Viability

In the simplified linear case developed above, the inequality (48.30) establishes that in the case of a fall, the motion of the COM diverges exponentially, so the integral of the norm of any n^{th} derivative of its position,

$$\int_{t_0}^{\infty} \|\mathbf{c}^{(n)}(t)\| dt, \quad (48.32)$$

would be infinite. Therefore, if we can find a finite value for such an integral from a given initial state of the robot, we can conclude that this state is viable.

48.3.4 Controllability

For any dynamical system, an initial condition \mathbf{x}_0 is *controllable* to a final state \mathbf{x}_f , if there exists a feasible input trajectory $\mathbf{u}(\cdot)$, which takes the system from \mathbf{x}_0 to \mathbf{x}_f . An initial state \mathbf{x}_0 is denoted *finite-time controllable* to \mathbf{x}_f if the minimum time required is finite. Controllability analysis is a well understood topic for linear dynamical systems, where a simple rank condition on the *controllability matrix* provides necessary and sufficient conditions to establish whether or not any initial condition can be driven to any final state [48.54]. For nonlinear systems, the property is dependent on both the initial and final states.

In the case of legged robots, instead of considering the set of all viable states introduced earlier, we could consider instead the more limited set of states that are controllable to stable fixed-points – states that can come to a stable stop after a given number of steps. This is a sufficient condition for viability. Such states have been called *capturable* [48.55], and arguably encompass most of the states of interest for legged robots. A variant would be to consider states from which the robot is able to reach a stable limit cycle, or any other state which is known to be viable in the first hand.

The Capture Point

In the simple linear case developed above, the capturable states can be identified analytically with the help of the compound variable

$$\boldsymbol{\xi} = \mathbf{c} + \frac{1}{\omega} \dot{\mathbf{c}}, \quad (48.33)$$

introduced independently as the *extrapolated center of mass* (XCOM) [48.56], the *capture point* [48.57] or the *divergent component* of the dynamics [48.58]. These three denominations correspond to three key properties of this variable. First of all, a trivial reformulation gives

$$\dot{\mathbf{c}} = \omega(\boldsymbol{\xi} - \mathbf{c}), \quad (48.34)$$

revealing that this point $\boldsymbol{\xi}$ is the point where the COM is converging to, hence the extrapolated COM. Following the linear dynamics (48.29), the horizontal motion of this point satisfies

$$\dot{\boldsymbol{\xi}}^{x,y} = \omega(\boldsymbol{\xi}^{x,y} - \mathbf{z}^{x,y}), \quad (48.35)$$

where we can see that this point $\boldsymbol{\xi}$ diverges away from the CoP \mathbf{z} . But if this point is above the support polygon,

Fig. 48.8 The speed of the COM c points towards the capture point ξ , while the speed of this capture point points away from the CoP, z . The combination of these two first-order dynamics gives the acceleration \ddot{c} , pushing the COM away from the CoP

if we have

$$\xi^{x,y} \in \text{conv} \{p_i^{x,y}\}, \quad (48.36)$$

we can have $z^{x,y} = \xi^{x,y}$ so the point ξ can stay motionless, and the COM will converge to it and come to a stop, hence it can be seen as a capture point (CP). Finally, we can observe that the second-order linear dynamics (48.29) has been decomposed here as two first-order linear dynamics (48.34) and (48.35), the first one being stable, with the COM converging to the XCOM, the second one being unstable, with the XCOM diverging away from the CoP, hence the divergent part of the dynamics (48.29). Here appears an interesting structure relating the motion of the points z , \dot{c} and ξ , shown in Fig. 48.8 [48.59, 60].

An important observation here is that if the state of the robot satisfies the condition (48.36), then the robot can stop without making any step and it is capturable and viable. Further analysis, considering any given number of steps and a nonzero angular momentum L can be found in [48.60].

48.3.5 Robust or Stochastic Stability

For the deterministic robot dynamics models described in Sect. 48.2, the concepts of fixed-points, limit cycles, viability, and controllability form the core issues of analysis. However, in the presence of disturbances, such as model inaccuracies or unpredicted variation in terrain, tools from robust verification must be called upon to characterize the stability of a system. Broadly speaking, robust stability analysis exists in two forms. In *worst-case* analysis, an upper bound is given for a disturbance and the goal is to demonstrate that for any

disturbance within this bound, the system will not reach an unstable state. Alternatively, *stochastic* analysis can be performed where a disturbance probability distribution is specified with the goal being to demonstrate that the system avoids unstable states with high probability. Worst-case analysis has received surprisingly little attention to date in the legged robotics community, however analysis approaches based on Lyapunov functions [48.38, 41, 47] can be easily extended using the notion of a *common Lyapunov function* [48.61]. One challenge here is that the nominal solutions, e.g., the exact shape of the nominal limit cycle, are often parameter dependent: the system might still be stable with different parameters, but to a slightly different limit cycle.

Stochastic stability has received relatively more attention in the legged robotics community, perhaps because many interesting models of possible disturbances do result in robots that walk for a long time, but do eventually fall over. Such systems cannot be classified as stable, but it seems incomplete to simply call them unstable. Such systems are said to be *metastable*, a concept first established in the physics community [48.62] and later used to analyze walking systems [48.63]. From this point of view, the stability of a system can be characterized by its mean time to failure.

Recall the idea of Poincaré maps described above, but now consider the discrete time stochastic return map dynamics for a periodic walking system,

$$x_{k+1} = r(x_k, h_k), \quad (48.37)$$

where $h_k \sim P(h)$ is a random variable that, e.g., captures the terrain height at time step k . Discretizing the state space $X \subseteq \mathbb{R}^{(N+6)} \times \mathbb{R}^{(N+6)}$ into d states allows us to define the Markov process based on the above return map

$$p_{k+1} = \mathbf{T}p_k, \quad (48.38)$$

where $p_k \in \mathbb{R}^d$ is the state probability distribution vector and \mathbf{T} is a stochastic matrix with entries $T_{ij} = \Pr(x_{k+1}^i | x_k^j)$. If we assume that all failure states are absorbing and can be grouped together into a single state, this corresponds to a column in \mathbf{T} containing a single 1 and $d-1$ zeros. The largest eigenvalue of \mathbf{T} must then be $\lambda_1 = 1$ with a corresponding eigenvector v_1 , describing the stationary distribution of the absorbing state. Interestingly, the second largest eigenvalue has been found to be close to unity $\lambda_2 \approx 1$ and much larger than the remaining $d-2$ eigenvalues, for several simple walking systems [48.63]. This suggests the existence of a metastable neighborhood in state space captured by the distribution v_2 with an associated time constant $\tau = -1/\log(\lambda_2)$. Other approaches to computing these stochastic stability bounds are also possible [48.64].

48.3.6 Input-Output Stability

Input-output methods define sensitivity measures to summarize the system's response to disturbances. For example, for a walking system, one could define a vector $I \in \mathbb{R}^m$ composed of m gait variables that directly relate to failure modes (such as foot-ground clearance) and measure the effect that a set of input disturbances w , have on their values. The *gait sensitivity norm* does exactly this [48.65]; here the dynamic system response $\|\partial I / \partial w\|_2$ is used as a measure of disturbance rejection. How is this response actually computed? In practice, computing the system response can be done experimentally by generating a variety of perturbations and measuring the effect in the gait variables. Although laborious, this approach is probably the most appropriate for physical systems. Alternatively, for simulated limit cycle walkers, linearization of the Poincaré return map and perturbation analysis yields a complete characterization of the dynamic system response.

More general tools from nonlinear control theory can also be applied. The L_2 gain is a sensitivity measure that has seen widespread application in nonlinear control theory. For complex dynamical systems such as walking robots, an upper bound on the L_2 gain can be approximated using storage functions, which can often be computed using convex optimization [48.66, 67].

48.3.7 Stability Margins

In practice, computing performance measures like the ones mentioned above for complex walking systems can be very difficult. As a result, researchers often employ heuristic stability margins to keep the robot away from the boundary of stability. Here the definition of stability can vary widely. The simplest stability margins rely only on the static configuration of the robot, where if the **COM** ground projection leaves the support polygon, this corresponds to an uncompensated moment on the foot resulting in a rotation along its edge. Popular static metrics include the distance between the ground projection of the **COM** and the edges of the support polygon or the minimum potential energy required to

tip the robot over sideways [48.68]. Because these stability criteria are based only on statics, they are only practically useful for slow (or *quasi-static*) motions.

The most commonly used dynamic stability margin requires that the **CoP** (or **ZMP**) remains within the boundary of the support polygon. When this condition is satisfied, the foot cannot rotate around the boundary of the support polygon. Note that this is certainly very conservative – many bipedal robots walk dynamically even with point feet (resulting in a **CoP** that is *always* on the boundary of the support polygon) – but this metric has proven extremely useful for flat-foot dynamic walking. Goswami introduced the related concept of the foot rotation indicator (**FRI**) [48.69] that is defined as the point on the ground where the net ground reaction force would have to act to keep the foot from rotating; this point need not stay inside the support polygon and can therefore be applied for a wider range of gaits. However, the stability claims based on these criteria are valid only on flat terrain and they do not constitute necessary or sufficient conditions for stable walking in general [48.15, 55].

When the **COM** projection exits the support polygon, there are two ways to make it return: by accelerating the **COM** in the direction of the support polygon through changes in angular momentum or by changing the support polygon by taking a step. This basic insight led to stability margins based on *capture regions* [48.55, 60]. A capture region is simply the set of all capture points (defined in Sect. 48.3.4). The *capture margin* is a metric that determines the *capturability* of a walking system. If the capture region and support polygon overlap, it is defined as the maximum distance between the points in the capture region and the closest edge of the support polygon, otherwise it is the negative distance between the capture region and support polygon. Note that large values under this metric are related to the total capture region area, which is in turn related to the ability of the walking system to stabilize itself, e.g., with upper body motions that affect angular momentum [48.60]. Extensions to n -step capture margins have also been developed and described in detail [48.55].

48.4 Generation of Dynamic Walking and Running Motions

As mentioned in the brief historical introduction to this chapter, early legged robots were maintaining quasi-static equilibrium postures at all time. The transition to more dynamic motions took place at the beginning of the 1980s, associated with biped [48.4] and mono-

pod [48.5] robots. As a result, this Section on dynamic legged locomotion will focus on results obtained mostly with biped robots, although most of the methods discussed here could be applied as well to other legged robots.

48.4.1 Early Offline Motion Generation Schemes

The very limited computing power of early robots allowed very limited online decisions. As a result, trajectories were usually computed offline, especially in complex situations such as for legged robots. Online motion generation has finally become possible only by the year 2000, thanks to the exponential increase in computing power and the continuous progress of numerical methods during the last decades.

Trajectory Optimization

One of the earliest approaches to computing walking and running motions was through numerical optimization [48.70]. The idea is to leverage the capacity of trajectory optimization methods to take into account nonlinear dynamics and objectives such as minimizing energy consumption, and compute the corresponding optimal motion. Unfortunately, the dynamics of legged robots are so complex that this approach was still stuck with simple planar models by the end of the 1990s [48.71–75]. It is only by the year 2000 that the first optimal walking motions for complete 3-D models could be computed [48.76, 77].

Fortunately, numerical methods have continued to improve (as discussed in Sect. 48.6.1), allowing researchers to solve complex problems such as optimizing trajectories and the mass distribution of the robot simultaneously and maximizing the open-loop stability of trajectories [48.78].

Unfortunately, this approach still requires time consuming computations that often cannot be realized online. Not being able to compute walking or running motions online limits the robots to a predefined set of precomputed actions, potentially ruining their versatility and reactivity. One way to alleviate this serious limitation is to generate a database of trajectories [48.79] that can be queried online, possibly conditioned on orders given to the robot [48.80] or the current state of the robot in order to improve its stability [48.40, 81, 82].

Artificial Synergy Synthesis and the ZMP Approach

Partitioning the problem is another early approach, that aimed at palliating the complexity of the dynamics of legged robots that hindered trajectory optimization. The idea is to assign some degrees of freedom of the robot to take care of dynamic constraints such as the ODI (48.13), allowing the rest of the robot to be operated more or less independently. This general approach has been called *artificial synergy synthesis* [48.10].

The original proposition in [48.10] was to use trunk rotations to ensure dynamic feasibility while the legs of

the robot executed a given prerecorded motion. More precisely, leg motions and contact points p_i being predefined, the trajectory of the CoP z could be predefined accordingly, so that it was just a matter of solving the ordinary differential equation (ODE) (48.13) for this predefined z to obtain the required rotations of the trunk. This original proposition was demonstrated experimentally 20 years later on the Waseda University WL-12RV biped walking robot [48.83]. This method of predefining the trajectory of the CoP has eventually been called the *ZMP approach* to walking motion generation (remember the ZMP is just another name given to the CoP). This ZMP approach has been associated later with having feet always flat on the ground, excluding heel and toe rotation phases. Note, however, that such phases were considered in the original proposition [48.10].

Some aspects of this proposition can be questioned. It has been argued first of all that predefining the evolution of the CoP is not necessary nor even desirable [48.84, 85]. Then, the ODI (48.13) clearly shows that dynamic feasibility depends on both variations of the angular momentum L , and motion of the COM c with respect to contact points, p_i . While trunk rotations mostly involve variations of the angular momentum, a recent analysis showed that this has only a weak influence on the balance of legged robots [48.86]. Dynamic feasibility can be handled much more efficiently by adapting the motion of the COM, which has been the prevailing approach.

The core idea of partitioning the motion of the robot builds on a profound and far-reaching observation: if the robot has a sufficient number of degrees of freedom and sufficient control authority, then every part of the motion that is not involved in the dynamic constraints – everything but angular momentum and motion of the COM with respect to contact points – can be operated more or less independently, and appears therefore to be relatively peripheral to the problem of legged locomotion. It is the same key observation that implicitly drives the templates and anchors approach and the long history of simple biomechanical models of legged locomotion that focus on a few meaningful degrees of freedom, mostly the motion of the COM with respect to contact points, and abstract all the rest [48.87–89]. This idea has been tremendously successful in the legged locomotion research community.

48.4.2 Online Motion Generation: A Model Predictive Control Point of View

If the algorithms for motion generation could work sufficiently fast to be applied online, then the robot

could achieve reactivity and robustness by continuously adapting the motions to the current state of the robot and its environment. But therein lies a problem: how can we make sure that the continuous re-evaluation of online decisions maintains long term viability? One solution comes from the model predictive control (MPC) theory.

The online motion generation schemes that allow most of the great humanoid robots of today and yesterday to walk and run can all be related to MPC theory and can all be seen as variants of the same MPC scheme, although they have rarely been introduced in that way. Most adopt the artificial synergy synthesis approach described in the previous Section, focusing almost exclusively on the motion of the COM with respect to contact points and assuming that the rest of the robot can be operated more or less independently.

Viability, Optimal Control and MPC

When trying to identify viable states in Sect. 48.3.3, the first option was to check if the integral (48.32) could have a finite value. A classical result from optimal control theory is that an optimal control law minimizing this integral would make it decrease with time. As a result, if this integral was finite in the beginning, it would stay finite: if the state of the robot was viable in the beginning, it would stay viable. The problem is, the dynamics of legged robots is too complex to be able to compute such an optimal control law in the general case.

MPC is one way to obtain a computable approximation to this optimal control law. The fundamental idea is to introduce a *terminal constraint* [48.90], imposing that the integral (48.32) is equal to zero after a finite length of time. Introducing such an artificial constraint naturally yields a suboptimal control law, but this allows considering the integral (48.32) over only a finite length of time while preserving viability. Note that enforcing viability in finite time means in this case enforcing capturability: here, the terminal constraint is a capturability constraint.

Many MPC variants have been proposed [48.91], but two extremes are going to be significant in the following. One extreme is to observe that minimizing an integral of the form (48.32) is not necessary to obtain a viable behavior: the terminal, capturability constraint can be sufficient in this respect [48.92]. In this case, however, it is not possible to continuously re-evaluate and adapt the motion to the state of the system: this must be done at carefully chosen moments, what limited the reactivity of the robots. The other extreme is to observe that the terminal constraint is not absolutely necessary [48.93]: simply minimizing a truncated version of the integral (48.32) over a sufficiently long but finite length of time can still lead to an integral de-

creasing with time, ensuring viability. In this case, it is possible to continuously re-evaluate and adapt the motion to the state of the system without any problem.

Let us see now how all this theory is applied to the online generation of walking and running motions. In all the following examples, the robot is supposed to walk on a flat horizontal ground.

Predefined Footsteps and Capturability Constraint

Let us have a look first at motion generation schemes implementing the original ZMP approach, with predefined footsteps and a predefined CoP, and considering a capturability constraint to ensure viability. Let us begin with the walking motion generation scheme implemented in the long series of Waseda University humanoid robots [48.94], which considers a four point mass model with predefined motion except for the horizontal motion of the waist and trunk masses which is assigned to follow a reference trajectory for the CoP. An iterative procedure based on fast fourier transforms is used then to solve the dynamics

$$\frac{\sum m_i(\ddot{c}_i^z + g^z)c_i^{x,y} - m_i \dot{c}_i^z \dot{c}_i^{x,y}}{\sum m_i(\ddot{c}_i^z + g^z)} \rightarrow \dot{z}_{\text{ref}}^{x,y} . \quad (48.39)$$

In order to execute this scheme online, a capturability constraint is introduced, imposing that the robot is always able to stop within two steps [48.95]. Unfortunately, details about the choice of the reference CoP and the exact terminal constraint are not disclosed.

The walking motion generation scheme implemented in the Munich University Johnny robot [48.96] considers only a three point mass model with predefined motion, except for the horizontal motion of the main mass in the trunk which is assigned to follow a piecewise linear reference trajectory for the CoP. One degree of freedom is left in this reference trajectory in order to impose a terminal constraint on the position of the COM at the end of the next two steps

$$\dot{c}^{x,y} = \dot{c}_{\text{ref}}^{x,y} . \quad (48.40)$$

This constraint appears to be incomplete in imposing capturability, what would require to consider also the velocity of the COM (Sect. 48.3.3).

The walking motion generation scheme implemented in the Honda Asimo robot [48.58] is very similar, three point masses and a piecewise linear reference for the CoP with one degree of freedom left to satisfy the terminal constraint. The difference lies in the terminal constraint which is a true capturability constraint, imposing cyclicity of the motion through the capture point/XCOM/divergent component of the dy-

namics at the end of the next step

$$\xi^{x,y} = \xi_{\text{ref}}^{x,y}. \quad (48.41)$$

The walking motion generation scheme implemented in the Tokyo University H7 robot [48.97] considers the whole dynamics (48.13) of the robot. The whole motion of the robot is predefined, except the horizontal motion of the COM which is assigned to follow a reference trajectory for the CoP, set in the middle of the contact points. An iterative procedure is used then to solve the dynamics

$$\mathbf{c}^{x,y} - \frac{m \mathbf{c}^z \ddot{\mathbf{c}}^{x,y} - \mathbf{S} \dot{\mathbf{L}}^{x,y}}{m(\ddot{c}^z + g^z)} \rightarrow \overline{\mathbf{p}}_i^{x,y}. \quad (48.42)$$

The terminal constraint (48.40) on the position of the COM (incomplete with respect to capturability) is also considered at the end of the next two steps.

The walking and running motion generation scheme implemented in the Toyota Partner robot [48.98] is exactly the same, except for the terminal constraint which is a true capturability constraint imposing cyclicity of the motion through both the position and velocity of the COM.

The walking and running motion generation scheme implemented in the Sony QRIO robot [48.99] follows a similar design, but considers only a single point mass at a constant height, with its horizontal motion assigned to minimizing the deviation of the CoP from the middle of the contact points

$$\min \int \left\| \mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} - \overline{\mathbf{p}}_i^{x,y} \right\|^2 dt, \quad (48.43)$$

while imposing a capturability constraint on both the position and velocity of the COM.

Another variant tested on the Kawada HRP-2 robot [48.100] also considers a single point mass at a constant height, but the CoP follows a piecewise polynomial trajectory

$$\mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} = \mathbf{z}_{\text{ref}}^{x,y}, \quad (48.44)$$

with some degrees of freedom left to satisfy the same capturability constraint as before, through both the position and velocity of the COM. An important characteristic of this scheme is that the piecewise polynomial trajectory of the CoP may fluctuate strongly, threatening to violate the ODI (48.13). An automatic adjustment of the step timings is proposed therefore in order to minimize this risk.

All of these walking and running motion generation schemes try to impose capturability through terminal

constraints, but some of them appear to fail properly doing so by only constraining the position of the COM. None of them consider an integral of the form (48.32): the integral (48.43) does not match. We have seen earlier that in this case, it is possible to re-evaluate and adapt the motion at specific instants, what has been done when having to realize new steps, or when changing the walking speed or direction. But to adapt the motion to a perturbation, a specific observer would be required to trigger the adaptation at the correct instant [48.92], and it appears that this option hasn't been investigated: no state feedback has been experimented with these motion generation schemes.

Predefined Footsteps, Without Capturability Constraint

In the standard walking motion generation scheme implemented in the Kawada HRP-2 humanoid robot [48.101], the whole motion of the robot is predefined as before, except the horizontal motion of the COM which is assigned this time to minimize the weighted integral

$$\min \int \left\| \ddot{\mathbf{c}}^{x,y} \right\|^2 + \beta \left\| \mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} + \frac{\mathbf{S} \dot{\mathbf{L}}^{x,y}}{mg^z} - \overline{\mathbf{p}}_i^{x,y} \right\|^2 dt \quad (48.45)$$

of the norm of the third derivative of the motion of the COM and the deviation of the CoP from a reference in the middle of the contact points. This is clearly an integral of the form (48.32), and we have seen that viability can be ensured in this case if we consider a truncated version of this integral over a sufficiently long but finite length of time, typically the next two steps, without the need to impose any terminal constraint. We have also seen that it is possible in this case to continuously re-evaluate and adapt the motion to the state of the system, a clear improvement over the previous approaches based solely on terminal constraints. This has been validated experimentally in various situations, effectively adapting the walking motion to perturbations [48.102].

An interesting variant [48.103] introduces variations of the angular momentum \mathbf{L} as an additional variable to minimize the combined integral

$$\min \int \left\| \ddot{\mathbf{c}}^{x,y} \right\|^2 + \beta \left\| \mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} + \frac{\mathbf{S} \dot{\mathbf{L}}^{x,y}}{mg^z} - \overline{\mathbf{p}}_i^{x,y} \right\|^2 + \gamma \left\| \mathbf{L}^{x,y} \right\|^2 dt, \quad (48.46)$$

showing an improvement in the tracking of the generated motion (and the same closed loop robustness to small perturbations).

A problem however with these approaches is that simply minimizing the deviation of the **CoP** from the middle of the contact points doesn't preclude it from fluctuating, so the **ODI** (48.13) could be violated, especially in case of perturbations. This is monitored in [48.102] to trigger a change of footstep if necessary, but without any clear guarantee that this change is appropriate. For this reason, it has been proposed in [48.85] to impose the **ODI** (48.13) as a strict constraint, considering a single point mass model with a constant height

$$\mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} \in \text{conv} \{ \mathbf{p}_i^{x,y} \}, \quad (48.47)$$

and simply minimize the integral

$$\min \int \|\ddot{\mathbf{c}}^{x,y}\|^2 dt \quad (48.48)$$

over a sufficiently long but finite length of time to ensure viability. This is the walking motion generation scheme implemented in the Aldebaran Nao robot [48.104].

A variant tested successfully on the **DLR** (Deutsches Zentrum für Luft- und Raumfahrt) biped robot [48.105] considers minimizing the deviation from a reference trajectory for the **XCOM** together with the derivative of the **CoP**

$$\min \int \|\dot{\xi}^{x,y} - \dot{\xi}_{\text{ref}}^{x,y}\|^2 + \beta \|\dot{z}^{x,y}\|^2 dt. \quad (48.49)$$

An additional terminal constraint was considered but not tested.

A last proposition, tested only in simple simulations, not with a real robot [48.106], considers a single point mass which is assigned to minimize the deviation of the leg length l from a given reference, and the deviation of the **CoP** from the middle of the contact points over the next two steps

$$\min \int (l - l_{\text{ref}})^2 + \beta \left\| \mathbf{c}^{x,y} - \frac{c^z}{\ddot{c}^z + g^z} \ddot{\mathbf{c}}^{x,y} - \overline{\mathbf{p}}_i^{x,y} \right\|^2 dt. \quad (48.50)$$

What makes this proposition particularly stimulating is that this is not an integral of the form (48.32), that can ensure viability, and no terminal constraint is there to impose capturability, so there is no direct relation with the viability/capturability analysis developed in Sect. 48.3.3, on which all the previous schemes were based. What this minimization only imposes is the ability to realize two more steps in the future, with legs approximately at a nominal length: the situation in the end of these two steps is not controlled (no terminal

constraint), so the robot might very well be falling afterwards. However, in the presented simulations, it appears that maintaining this ability to make two more steps in the future is a sufficient condition for generating stable walking and running motions. The conclusion is that terminal constraints or integrals of the form (48.32) are in fact not mandatory and could be relaxed altogether.

In all of these approaches, the footsteps were predefined and kept fixed, which is obviously a strong limitation on the robot's capacity to adapt to a changing environment or to strong perturbations.

Adaptive Footsteps

In fact, adapting foot placement is straightforward, and has already been validated on a Kawada HRP-2 robot [48.107]: the only required change is to consider foot placement as a decision variable, used in addition to the horizontal motion of the **COM**, in order to both satisfy the **ODI** (48.47) and minimize the integral

$$\min \int \|\dot{\mathbf{c}}^{x,y} - \dot{\mathbf{c}}_{\text{ref}}^{x,y}\|^2 dt \quad (48.51)$$

over a sufficiently long length of time to ensure viability (since this is clearly an integral of the form (48.32)), and have the **COM** follow on top of that the reference velocity $\dot{\mathbf{c}}_{\text{ref}}^{x,y}$. Now, since the footstep placement is decided online, geometric feasibility needs to be checked online as well. A simple but effective option is to consider a polygonal approximation of the reachable volume of the **COM** with respect to each foot on the ground [48.108].

Yet, the timing of the steps was still predefined, what has a huge influence on the reactivity of legged robots [48.60]. In order to adapt it as well, it has been proposed in [48.109] to minimize the combined integral

$$\min \int \|\dot{\mathbf{c}}^{x,y} - \dot{\mathbf{c}}_{\text{ref}}^{x,y}\|^2 + \|\ddot{\mathbf{f}}^{x,y}\|^2 dt, \quad (48.52)$$

with $\ddot{\mathbf{f}}^{x,y}$ the horizontal acceleration of the feet. But this approach has been tested only in simple simulations so far. Moreover, the underlying optimization problem becomes nonlinear, what is significantly more involved to solve.

Another approach, quite unique, starts with a singular linear quadratic regulator (**LQR**) design [48.110], considering the classical single point mass at a constant height, assigned to minimize the deviation of the **CoP** from a combination of a reference **CoP** and the **XCOM**

$$\min \int \left\| \mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} + \alpha \mathbf{z}_{\text{ref}}^{x,y} - (1 + \alpha) \xi^{x,y} \right\|^2 dt \quad (48.53)$$

for some $\alpha > 0$. An interesting feature of this singular **LQR** design is that it can be solved analytically. And an

interesting property of this singular objective function is that it can be reduced to zero, in which case we have

$$\mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} = (1 + \alpha) \xi^{x,y} - \alpha \mathbf{z}_{\text{ref}}^{x,y}, \quad (48.54)$$

what can be combined with the dynamics (48.35) of the **XCOM** to obtain a stable first order dynamics

$$\dot{\xi}^{x,y} = \alpha \omega (\mathbf{z}_{\text{ref}}^{x,y} - \xi^{x,y}), \quad (48.55)$$

according to which the **XCOM** ξ is going to converge to $\mathbf{z}_{\text{ref}}^{x,y}$, and the **CoP** \mathbf{z} as well according to (48.54). But in a very unusual twist, this **LQR** design is not used as is, and is inverted analytically to find under which condition does a piecewise constant trajectory of the **CoP** generate a nondiverging motion of the **COM**. Unsurprisingly, this nondiverging condition ends up being a terminal constraint on the capture point/**XCOM**/diverging part of the dynamics, with trajectories corresponding in the end exactly to those found in [48.59]. But here, this terminal constraint is used in the end to decide online the footstep placement that will ensure viability, what is eventually validated experimentally with very strong perturbations.

All Variants of a Common Design

The viability analysis of Sect. 48.3.3 attested the crucial importance of anticipation to avoid falling. We observe now that the walking and running motion generation schemes that power most of the greatest humanoid robots of today and yesterday, the Honda Asimo, the Toyota Partner, the Sony Qrio, the Aldebaran Nao, the Kawada HRP-2, the Tokyo University H7, the Munich University Johnny, the **DLR** biped, the long series of Waseda University humanoids and many others, are all structured around this necessity to anticipate, at least a couple steps ahead of time. Viability is secured then in different ways, always related to **MPC** theory, through capturability or through minimizing an integral of the form (48.32). In all cases, adopting the artificial synergy synthesis approach, focusing on the motion of the **COM** of the robot with respect to contact points, considering that the rest of the motion can be handled more or less independently, is the key to enable efficient computations. All these motion generation schemes appear then to share the same general design: **MPC** of the **COM** of the robot with respect to contact points. The rest is details.

The compelling consequence of identifying this common design, is revealing the possibility to cross-breed all these approaches, retaining the best features of each: more precise multiple mass models, for generating both walking and running motions, with adaptive footstep placement and adaptive timing, sensor feed-

back, all in order to obtain in the end the ultimate robust and versatile online motion generation scheme. These are the next obvious steps.

Missing in this gallery of great legged robots, the Boston Dynamics biped and quadruped robots. They are without a doubt the legged robots exhibiting the most impressive dynamic motions today, robust and versatile. Exact details about their control algorithms are scarce, but various clues suggest that they might share the same design.

48.4.3 Motion in Constrained Environments

We have seen so far how to generate dynamic walking and running motions by considering the dynamic feasibility constraint (48.13) independently from any other concern. But on truly rough terrain or in cluttered spaces, kinematic constraints on the motion of the robot cannot be disregarded and can further complicate the problem. More precisely, kinematic constraints generally make the reachable space of the robot non-convex, so that deciding actions and motions with only a local view on the situation can quickly get the robot stuck in local loops or dead-ends. One way to decide actions and motions with a global view on the situation is with planning techniques, as described in Chap. 7 on motion planning and Chap. 47 on motion planning and obstacle avoidance. In the case of legged robots, three classes of problems of increasing complexity have been considered: dynamic manipulation without locomotion, locomotion on a flat ground with obstacles, and locomotion on rough terrain with complex contact transitions.

Dynamic Manipulation Without Locomotion

In the case of manipulation tasks without locomotion, the only difference of legged robots with respect to more traditional manipulator robots is the dynamic feasibility constraint (48.13). Therefore, a mere application of the standard planning techniques described in Chaps. 7 and 47 including this feasibility constraint has proved to be fully sufficient. But these techniques are strongly biased towards quasi-static motions. As a result, a sequence of statically stable postures is computed first, and the motion is smoothed and accelerated afterwards, finally taking into account dynamic feasibility [48.111]. Much more involved are the problems involving locomotion, which attracted therefore much more attention.

Legged Locomotion on a Flat Ground with Obstacles

If we consider that the problem of generating dynamic legged locomotion is properly solved thanks to the dif-

ferent methods described earlier in this section, we can try to abstract its details and plan the navigation of the upper body of a legged robot between obstacles as for any other mobile robot, with the same planning techniques, regardless of the exact locomotion method. It has been shown indeed that legged robots present a form of *small-space controllability*, which means that their upper-body can follow any given path with any given accuracy [48.112], although this can require impractically quick steps. A different option to follow exactly any given path with the upper-body is to cross legs, as if walking on a balance beam, and some robots have been specifically designed to be able to realize such feats [48.113], but this can require impractically slow steps. Ruling out impractically slow or impractically quick steps, the legged locomotion may finally differ from the planned path and fail to avoid obstacles. In this case, iterative replanning techniques have been proposed [48.114].

In this approach, however, it is assumed that finally finding proper footholds to follow the path planned for the upper body is not a problem. Yet, the appeal of legged robots is to provide improved mobility on difficult terrain, situations where finding footholds is actually a problem. A solution then is to check the availability of proper footholds when planning the upper body motion [48.115], an approach recently refined to show how to obtain in the general case an exact equivalence between planning a continuous path and planning a sequence of footholds on a flat ground [48.116, 117].

A different approach is to plan directly the footholds with respect to obstacles on the ground, and generate afterwards the corresponding dynamic legged locomotion [48.118]. This has been applied successfully to long distance navigation with a tiered strategy [48.119], with computations fast enough to run online in changing environments [48.120], taking into account deterministically moving obstacles [48.121], on mildly rough terrain [48.122–124], using on-board sensing [48.125]. Obstacles above the ground can be considered then with a hybrid bounding box or more refined swept volumes [48.126, 127], or one can approximate the free-space with convex segmentation [48.128].

Legged Locomotion with Complex Contact Transitions

On truly rough terrain or in cluttered environments, legged locomotion may require much more complex contact situations and contact transitions than in standard walking or running, involving not only contacts between the feet and the ground, but all potential contact surfaces on the robot and on the environment. The variability of these situations is beyond comparison with the previous case on flat ground, and chances of

precomputations or simplifications are strongly lacking in respect. Notably, the kinematic and dynamic constraints cannot be tackled independently, and having to consider them simultaneously results in an overwhelming computational problem. As a result, a major effort has been to find a proper ordering of the different sub-problems in order to obtain a tractable problem in the end, finally opting for planning contacts before motion [48.129–131]. Complex real-life use-cases have been solved this way [48.132–134], but the computational requirements still limit our ability to achieve the versatility of locomotion possible on flat ground. On-line adaptation to changing environments has yet to be convincingly demonstrated and remains an active area of research.

As noted before, the underlying planning techniques manifest a strong bias towards quasi-static motions: some post-processing is necessary to obtain a truly dynamic motion in the end. The same two options as in Sect. 48.4.1 have been proposed, standard trajectory optimization [48.135], or following the artificial synergy synthesis approach and computing first the motion of the COM of the robot with respect to the different contact points, independently from the rest of the motion of the robot, which is computed only afterwards [48.21]. But the strong interdependency between kinematic and dynamic constraints defeats the core assumption of the artificial synergy synthesis approach in this case: dynamic feasibility can't always be handled independently from the rest of the motion of the robot, so there is a significant risk that this method fails finding in the end a feasible motion even if one exists.

Further discussion of all these problems in the specific case of humanoid robots can be found in Chap. 67.5 on whole-body activities of humanoid robots, or in [48.136]. There is also a rich literature on gait selection for many-legged robots, starting as early as [48.137] but this is still an active area of research [48.138].

48.4.4 Motion Generation with Limited Computing Resources

The walking and running motion generation schemes presented so far in this chapter all require significant computation, even when they consider only simplified dynamical models. Early legged robots, which had very limited computing resources, had to rely on much less demanding approaches. One option is to combine simple explicit rules, each one focusing on a different part of the overall motion. Another option is to try to mimic biological hypotheses on how animals generate and control their motion, what ended up in fact with somehow similar propositions.

Combining Simple Rules

Thanks to simplifying symmetries in biped or quadruped running gaits such as trot, pace and bound, the whole family of robots hopping in the MIT LegLab throughout the 1980s on one, two or four legs, in 2-D (two-dimensional) or 3-D (three-dimensional), could rely on the same simple control design [48.5]. The general idea is to apply simple control laws independently to the different parts of the overall locomotion task. The vertical oscillations were controlled by open-loop vertical thrusts, simply stabilized by mechanical energy losses. Since the angular momentum is conserved during flight phases, the body attitude was controlled only during stance phases, with standard proportional–derivative (PD) control. The key to maintaining long-term balance, and controlling the global motion was foot placement. An elementary analysis of the motion of the COM during the stance phase revealed the role of the so-called *neutral* foot position, which would make the stance phase perfectly symmetric. It is then just a matter of linear corrections of the foot position with respect to this neutral position to make the stance phase asymmetric in order to control the robot's speed and balance. The direct combination of these utterly simple control laws resulted in impressively robust and versatile locomotion.

The first biped robot that walked dynamically relied on an equally simple approach [48.4]. This robot emulated walking on stilts, with contact surfaces between the feet and the ground reduced to single points, so $z = p$. With a single, fixed contact point during single support phases (the double support phases were supposed negligible), the ODI (48.29) can be solved analytically: for $t \geq t_0$,

$$\begin{pmatrix} \mathbf{c}^{x,y}(t) - \mathbf{p}^{x,y}(t_0) \\ \dot{\mathbf{c}}^{x,y}(t) \end{pmatrix} = \mathbf{A}(t) \begin{pmatrix} \mathbf{c}^{x,y}(t_0) - \mathbf{p}^{x,y}(t_0) \\ \dot{\mathbf{c}}^{x,y}(t_0) \end{pmatrix} \quad (48.56)$$

with

$$\mathbf{A}(t) = \begin{pmatrix} \cosh \omega(t-t_0) & \omega^{-1} \sinh \omega(t-t_0) \\ \omega \sinh \omega(t-t_0) & \cosh \omega(t-t_0) \end{pmatrix}, \quad \omega = \sqrt{\frac{g^z}{c^z}}. \quad (48.57)$$

If the next single support phase starts at time t_1 with a foot position $\mathbf{p}^{x,y}(t_1)$, we end up having

$$\begin{pmatrix} \mathbf{c}^{x,y}(t_1) - \mathbf{p}^{x,y}(t_1) \\ \dot{\mathbf{c}}^{x,y}(t_1) \end{pmatrix} = \mathbf{A}(t_1) \begin{pmatrix} \mathbf{c}^{x,y}(t_0) - \mathbf{p}^{x,y}(t_0) \\ \dot{\mathbf{c}}^{x,y}(t_0) \end{pmatrix} + \begin{pmatrix} \mathbf{p}^{x,y}(t_0) - \mathbf{p}^{x,y}(t_1) \\ 0 \end{pmatrix}, \quad (48.58)$$

which describes the motion of the COM $\mathbf{c}^{x,y}$ with respect to the contact points $\mathbf{p}^{x,y}$, from one step, starting at time t_k , to the next, starting at time t_{k+1} . This discrete time dynamical system can be controlled then with the foot placement $\mathbf{p}^{x,y}(t_k)$. Since it is linear, standard pole placement can be applied, yielding a standard PD control of foot placement. This simple approach has been successfully applied on more complex biped robots [48.139, 140].

The drawback of combining independent control laws is to lack coordination yielding potentially harsh, unrefined motion, but this approach demonstrates that stable locomotion is possible even with very limited control resources. Of primary importance here are foot placement and upper body attitude; the rest of the motion appears to be secondary, at least with respect to balance control. Pushing this observation further, it has been proposed, and validated in simulation, that a large variety of walking patterns could be used, and stabilized only with upper body attitude and foot placement control, both with simple PD control laws [48.141]. It is not surprising then that hand-designed motion patterns can be used successfully on robots as complex as the Korea Advanced Institute of Science and Technology (KAIST) Hubo humanoid robot [48.142], although this may require delicate fine tuning.

Reducing even further the control requirements, the mechanics of the robots could be tuned so that passive motions would automatically land the feet on the appropriate locations with respect to stability, ending up with perfectly passive stable dynamic locomotion. This idea will be discussed more thoroughly in Sect. 48.6.

Biomimetic Motion Generation

Current theories on locomotion control in animals include central pattern generators (CPGs) and cascades of reflex motions, which interact and combine to generate the final motion. CPGs are tunable oscillators, generating synchronized quasi-cyclic motion patterns in response to simple control signals such as locomotion speed or turning angle [48.143]. In order to introduce such CPGs in legged robots, standard oscillators such as the Van der Pol equation or the Hopf oscillator have been proposed [48.144, 145], or more biologically inspired neural oscillators [48.146] (ironically, *central* pattern generators often happen to be *decentralized*, composed of a collection of synchronized oscillators [48.143, 145, 147]).

But CPGs are intrinsically open-loop motion generators, so to stabilize and adapt the motion of the robot to their environment, limited feedback loops have been introduced, similar to the simple control laws discussed earlier in this Section, focusing on upper body attitude and foot placement [48.145, 147, 148]. Contin-

uing with the biological analogy, these simple feedback loops have been called reflexes. Following ideas discussed more thoroughly in Chap. 13 on behavior-based systems, the *subsumption architecture* has been proposed to build much more complex networks of reactive behaviors or reflexes [48.149], and has allowed a hexapod robot to walk successfully on mildly rough terrain without any careful planning of the motion [48.150].

Fundamentally the Same Decoupling Approach

Being inspired by simple mechanical analyses or by animals, these approaches based on combinations of

simple rules demonstrate that stable walking can be realized without much computation, at least in simple situations. More complex situations may require more refined motions and therefore more refined motion generation schemes, such as the ones discussed earlier in this chapter. But it is striking to observe again the same focus here on the motion of the **COM** of the robot with respect to the contact points, when controlling either the upper body attitude or the foot placement (or both), regardless of the rest of the motion, which can be generated by **CPGs**, inverse kinematics or any other approach, simple or complex. This is fundamentally the same decoupling as proposed earlier with the artificial synergy synthesis approach.

48.5 Motion and Force Control

Properly executing the walking and running motions computed in the previous section requires precise control of the motion of the robot and of the contact forces with the environment, applying techniques from Chapters 8 and 9 on motion and force control. But since legged robots are often complex mechanical systems with many degrees of freedom and some form of redundancy, techniques from Chap. 10 on redundant manipulators also need to be applied frequently. And in case of contact with multiple surfaces, problems of contact force distribution appear, requiring techniques similar to those found in Chap. 38 on grasping. And in the opposite case, during flight phases, when the robot is not at all in contact with its environment, its dynamics appear to share important properties with free-floating space robots, requiring control techniques similar to those found in Chap. 55 on space robotics. All these techniques (and many more) are necessary to make legged robots walk and run efficiently. The purpose of this Section is to see how they connect and are implemented in the case of legged robots.

Whole-Body Motion

Humanoid and other legged robots are often complex mechanical systems with a large number of degrees of freedom in order to accomplish the various kinematic and dynamic tasks necessary for simultaneously achieving locomotion, perception and manipulation of the environment, interaction with humans, etc. Making use of all available degrees of freedom, and not only those in the legs, to achieve multiple simultaneous objectives, and not only locomotion, is usually called *whole-body motion control* (Chap. 67.5). We have seen previously that locomotion mostly involves the motion of the **COM** c with respect to points p_i of contact with the environment. Other objectives involve end-effector motion for

manipulation, gaze control for perception, motion of specific parts of the robot for obstacle avoidance, etc. In all of these cases, what needs to be controlled is Cartesian motion of different parts of the robot, rather than joint motion. Several control schemes have been proposed to do this, standard inverse kinematics followed by joint space control [48.139], virtual model control [48.151], the task function approach [48.152, 153], operational space control [48.154].

Interestingly, the last two options allow specifying different priorities to the different objectives assigned to the robot, so in case these objectives are not feasible jointly, the robot tries first to achieve the objectives with higher priority. In the case of legged robots, maintaining balance and avoiding falls appear to be of primary importance for the safety of both the robot and its environment, so being able to consider this objective with a higher priority can be crucial in this regard. These control schemes allow moreover some form of decoupling between the different objectives, further contributing to the artificial synergy synthesis approach introduced earlier in the previous Section. We are going therefore to continue focusing here exclusively on the locomotion objective, since the other ones can be considered more or less independently and are not specific to legged robots.

Flight Phases

We have seen earlier in this chapter that during flight phases, when a legged robot is not in contact with its environment, the motion of the **COM** invariably follows a standard falling motion: there is no possibility to make it move in any other way. But we have seen that even though the angular momentum L is constant during flight phases, the joint configuration \hat{q} and the global orientation θ_0 of the robot can still be driven

concurrently together to any desired value thanks to the nonholonomy of the angular momentum (48.5). However, a famous theorem due to Brockett [48.155] implies that continuous time-invariant feedback control laws such as those proposed in [48.156, 157] are not able to do so. The solution is to use discontinuous or time-varying control laws [48.158], an approach well established in space robotics [48.159, 160].

In the case of running motions, it has been proposed to specifically adapt leg trajectories during flight phases in order to control both the joint configuration and the global orientation at the end of the flight phases [48.161]. It has been measured indeed that a simple difference in the height of a single step can result in 1 or 2 degrees of difference in the global orientation of the robot [48.8]. Albeit small, this effect is far from negligible. More thorough discussions of nonholonomic constraints and the impact of Brockett's theorem can be found in Chap. 49 on the modeling and control of wheeled mobile robots or in [48.158].

Angular Momentum

Either considering the ODI (48.13) when walking on a flat ground, or the Newton and Euler equations (48.3) and (48.4) in the general case, the dynamic feasibility of legged motions appears to be directly and entirely related to the motion of the COM \mathbf{c} , and the angular momentum, \mathbf{L} . It has been naturally proposed therefore to control specifically those two quantities concurrently [48.162–164]. Of course, since COM motion and angular momentum are directly related to contact forces \mathbf{f}_i (or equivalently to the CoP, \mathbf{z}), controlling the former is absolutely equivalent to controlling the latter. The question however is whether the angular momentum should be specifically controlled to some given value and what that value should be [48.163, 164].

Of course, since the angular momentum is directly related to contact forces, it should comply with the unilaterality and Coulomb friction limitations on contact forces (48.11) and (48.17). As a matter of fact, the regulation of angular momentum has been discussed only in quasi-static situations [48.162–164], where the reference value is clearly zero, which generally complies well with these limitations. And in the only case where walking was considered, the horizontal angular momentum $\mathbf{L}^{x,y}$, that appears in the ODI (48.13) when walking on a flat horizontal ground, was explicitly not controlled [48.162]. It appears, in fact, that during walking motions, the question of which value the angular momentum should have is very intricate, because of its nonholonomy, but it is definitely not zero [48.8, 103].

Even in quasi-static situations, both joint configuration and global orientation can be controlled independently from the angular momentum; the connection

between these different values is very subtle. As a result, controlling the angular momentum does not induce a control of either joint configuration or global orientation (due to its nonholonomy). The opposite is true however: controlling joint configuration and global orientation does induce a control of the angular momentum as a derived quantity. It has been argued furthermore that common whole body motion objectives such as manipulation or interaction with humans are more directly related to joint configuration and global orientation than to angular momentum [48.165]. As a matter of fact, disregarding the exact variations of the angular momentum has been the most frequent option so far [48.139, 151–154, 165]. In the end, it is not clear if specifically controlling the angular momentum can help controlling legged robots: this is still an open question.

COM Motion Control

Putting the angular momentum aside, and considering only the simple linear dynamics (48.29) when walking on a flat ground, and more precisely its decomposition (48.34) and (48.35), we have seen that every state satisfying the condition (48.36), such that the capture point ξ is in the support polygon, is capturable and can therefore be stabilized. If the capture point is strictly inside the support polygon, the COM can even be stabilized to any reference position \mathbf{c}_{ref} above the support polygon, with a simple linear feedback of the capture point

$$\mathbf{z}^{x,y} = \mathbf{c}_{\text{ref}}^{x,y} + k(\xi^{x,y} - \mathbf{c}_{\text{ref}}^{x,y}), \quad (48.59)$$

where the feedback gain $k > 1$ must be tuned in order to keep the CoP \mathbf{z} within the support polygon, ensuring dynamic feasibility of the motion. Indeed, using this feedback with the dynamics (48.35) yields a stable closed loop dynamics

$$\dot{\xi}^{x,y} = \omega(k-1)(\mathbf{c}_{\text{ref}}^{x,y} - \xi^{x,y}), \quad (48.60)$$

according to which the capture point ξ will converge to the reference position \mathbf{c}_{ref} , and the COM \mathbf{c} will converge to it as a result of the stable dynamics (48.34). It has been shown that among all proportional-derivative (PD) feedback of the motion of the COM

$$\mathbf{z}^{x,y} = \mathbf{c}_{\text{ref}}^{x,y} + k(\mathbf{c}^{x,y} + \lambda \dot{\mathbf{c}}^{x,y} - \mathbf{c}_{\text{ref}}^{x,y}), \quad (48.61)$$

the feedback (48.59) of the capture point, with a choice of $\lambda = \omega^{-1}$, is the only one that will successfully stabilize all capturable states [48.166]. It has been successfully applied to walking motions on the DLR biped robot [48.59].

Now, if there is a time-varying perturbation or error $\boldsymbol{\varepsilon}$ in our dynamics, such that

$$\mathbf{c}^{x,y} - \frac{c^z}{g^z} \ddot{\mathbf{c}}^{x,y} = \mathbf{z}^{x,y} + \boldsymbol{\varepsilon}, \quad (48.62)$$

the PD feedback (48.61) can be shown to be robustly stable (input-to-state stable, to be precise) with respect to ϵ , but with $\lambda < \omega^{-1}$ and $k > \frac{1}{\lambda^2 \omega^2}$ [48.167]. As discussed above, with this choice of λ , not all capturable states will be stabilized successfully, even if there is no perturbation. This is unfortunately a usual trade-off in robust control.

Force Feedback

Motion control of legged robots without contact force sensing and feedback has been shown to be possible for simple quasi-static balancing tasks, using passivity based control [48.168]. However, force sensing and feedback is commonly used when realizing more dynamic motions such as walking or running. One of the first problems to overcome in this case is the compliance of both the robot and its environment, which easily generates destabilizing oscillations [48.169–172]. Contact force control schemes of various complexity have been proposed, but always with the goal of damping these undesired oscillations. The exact implementation of these force control schemes generally relies on a stiff lower-level joint motion control in order to enhance disturbance rejection, leading to admittance control implementations [48.139, 169–173]. More details on such control schemes can be found in Chap. 9 on force control.

Now, these damping control schemes inevitably introduce some delay in the realization of the desired contact forces. One option is to show that the COM motion control scheme described earlier, which entirely relies on contact forces, is robust to such delay [48.59]. Another option is to take this delay into account with a simple first-order dynamics of the CoP

$$\dot{z} = \omega_z(z_d - z), \quad (48.63)$$

and adapt the previous COM motion control scheme accordingly [48.174, 175]

$$\dot{z}_d^{x,y} = \dot{c}_{\text{ref}}^{x,y} + k(\xi^{x,y} - c_{\text{ref}}^{x,y}) + k'(z^{x,y} - c_{\text{ref}}^{x,y}). \quad (48.64)$$

This introduces some force feedback directly in the COM motion control through the measurement of the CoP z , what can help improve the reactivity of the controller to perturbations.

Contact Forces Distribution

In case of contact with multiple surfaces, computing contact forces f_i , that allow realizing the desired motion control scheme through the Newton and Euler equations (48.3) and (48.4), and yet comply with both the unilaterality condition (48.11) and the Coulomb friction model (48.17), can be slightly more involved. The standard approach is through optimization, and more

precisely quadratic programming (QP) with linear constraints, using a faceted, linear approximation of the Coulomb friction model (48.17)

$$A f_i \leq b. \quad (48.65)$$

It has been proposed then to minimize when possible the norm of the joint torques u in order to reduce energy consumption [48.152],

$$\min_{f_i} \|u\|^2, \quad (48.66)$$

or to balance the contact forces between the different contact points, either by minimizing the sum of their norms [48.165],

$$\min_{f_i} \sum_i \|f_i\|^2, \quad (48.67)$$

or the norm of their difference [48.176],

$$\min_{f_i} \|f_{\text{left}} - f_{\text{right}}\|^2, \quad (48.68)$$

or minimizing the tangential forces in order to reduce the risk of slipping [48.177],

$$\min_{f_i} \sum_i \|f_i^{x,y}\|^2. \quad (48.69)$$

More general QP formulations have been proposed [48.178, 179], including hierarchies of kinematic and dynamic tasks and constraints [48.153].

But contact forces obtained in these ways are not explicitly kept away from the edges of the friction cone and unilaterality condition, so that the slightest perturbation may quickly lead to sliding or tipping, what can lead to serious issues. The simplest way to steadily improve the robustness of the robot to such perturbations is to introduce a security margin w

$$A f_i \leq b - w \mathbf{1}, \quad (48.70)$$

where $\mathbf{1}$ is a vector of ones, but there is no obvious way to decide which value would be appropriate. One option then is to try to maximize it with a linear program (LP)

$$\max_{w, f_i} w, \quad (48.71)$$

improving as much as possible the robustness of the robot to perturbations by selecting contact forces f_i the farthest possible from the edges of the (faceted) friction cone and unilaterality condition. Note that the maximal value w^* obtained in this way is the *residual radius* discussed in [48.19].

48.6 Towards More Efficient Walking

Examples of remarkably efficient locomotion are ubiquitous in nature. From sprinting cheetahs to leaping sifakas, the variety and beauty of animal motion has inspired roboticists for decades. Yet some of the most impressive examples of humanoid walking, e.g., Honda's Asimo or Boston Dynamics' Atlas, have employed high-impedance joint control to achieve stable locomotion. As a result, the fluidity of their motions is far from that of their biological counterpart. Indeed, these robots expend an order of magnitude more energy than a typical human while walking [48.180].

In contrast, the passive dynamic walking machines of McGeer and others [48.6, 181] have been able to achieve surprisingly human-like gaits without any actuation, relying solely upon their carefully designed body dynamics. These machines moved down sloped terrain, relying upon the conversion of potential to kinetic energy to balance the losses introduced by impacts and friction. Subsequent examples of minimally-actuated bipeds capable of walking under their own power on flat terrain made the first steps toward realizing efficient walking machines [48.180, 182].

The existence of these robots leads to several interesting questions. For example, how can we find limit cycles of underactuated walkers and reason about their stability? Simple models of walking systems have been used to try to answer these questions for over two decades. Such analyses typically rely upon linearization of the model dynamics to integrate the equations of motion or numerical simulation of the nonlinear dynamics

and analysis via Poincaré maps (Sect. 48.3.2). For example, the compass gait model is one of the simplest walking models, consisting of three point masses – one at the hip and one on each leg – and the legs connected to the hip with a pin joint (Fig. 48.10). Although even this very simple model cannot be analyzed analytically, a variety of stable gaits have been identified using numerical techniques [48.186].

Today there exists a community of researchers working to bridge the gap between stable and versatile machines like Asimo and efficient dynamic walkers. Topics of particular interest include navigating robustly over rough terrain, generating and stabilizing nonperiodic gaits, and scaling up to more complex robot models. New computational tools for generating and stabilizing trajectories for underactuated dynamical systems have been an important result of this work. In this section we highlight the fundamental insights provided by work on passive dynamic walking machines and describe ways in which these ideas have been extended to more general systems.

48.6.1 Gait Generation for Dynamic Walking

The most direct approach to producing efficient walking gaits in underactuated robots is to design controllers that produce actuated trajectories that mimic passive ones. Fundamental to these methods is the idea of restoration of mechanical energy. Since mechanical energy is

Fig. 48.9a–f Passive-dynamic walking machines. **(a)** The Wilson Walkie (after [48.183]). **(b)** A slightly improved version (after [48.184]). Both **(c)** and **(d)** walk down a slight ramp with the *comical, awkward, waddling gait of the penguin* (after [48.183]). **(e)** Cornell copy (after [48.185]) of McGeer's capstone design. This four-legged *biped* has two pairs of legs, an inner and outer pair, to prevent falling sideways. **(f)** The Cornell passive biped with arms (photo by Hank Morgan) (after [48.181]). This walker has knees and arms and is perhaps the most human-like passive-dynamic walker to date (photo reproduced with permissions from [48.180])

Fig. 48.10 The compass gait

lost at each heel strike, passive dynamic walkers require gravitational force to restore energy to the system before the next step. By choosing control inputs that regulate mechanical energy, for example by simulating gravity, walking on level terrain can be achieved [48.187, 188]. However, such approaches are still largely limited to modest terrains and periodic motions.

Trajectory optimization methods offer the potential to move beyond limit cycle gaits and to more complicated systems without passive stability properties. However, the fact that walking systems must make and break contact with the world complicates the trajectory optimization problem. Simulating rigid-body contact forces continuously using spring and damper models often results in stiff differential equations that can lead to numerical and computational issues. An alternative approach is to capture discontinuities in velocity by modeling collisions as impulsive events using a hybrid system representation (Sect. 48.2.3). For a walking hybrid system, a set of autonomous *guard functions* are defined such that $\phi_i(\mathbf{q}) = 0$ implies that body i is in contact and $\phi_i(\mathbf{q}) > 0$ implies the opposite. When a body comes into contact, the generalized velocity undergoes an instantaneous change, $\dot{\mathbf{q}}^+ = f_\Delta(\mathbf{q}, \dot{\mathbf{q}}^-)$, where $\dot{\mathbf{q}}^-$ and $\dot{\mathbf{q}}^+$ are the velocities pre and post-impact, respectively. The *mode* of the system is defined by the set of active contacts, $C = \{i | \phi_i(\mathbf{q}) = 0\}$, which in turn defines the set of Jacobian matrices in (48.2).

The hybrid system representation creates several challenges for trajectory optimization methods. The discontinuities due to mode transitions are typically accounted for explicitly using either *direct* or *multiple-shooting* methods [48.189]. Since each mode implies a different dynamics and mode changes are necessary for walking, this leads to the question of how to formulate the dynamics constraints. One solution is to predefine the sequence of mode transitions. For simple models with point feet, this approach can work quite well. However, for more complex models with many contacts, the number of modes grows

exponentially, making mode sequence prespecification impractical.

The complementarity-based methods for simulating rigid body systems in contact described in Sect. 48.2.3 suggest another approach. By discretizing the dynamics in time and considering only the integral of contact forces over a time interval, the forward dynamics of a walking system can be greatly simplified. Since many trajectory optimization methods already discretize by evaluating a finite set of points along a trajectory, incorporation of contact forces as optimization variables leads to trajectory optimization as a nonlinear optimization problem with complementarity constraints [48.37].

Many impressive examples of trajectory optimization for walking and running exist in the literature. For example, *Mombaur* [48.78] simultaneously optimized motion and physical parameters for simulated bipeds to achieve open-loop stable running and *Remy* [48.190] applied trajectory optimization to generate efficient running for a quadruped. There are many more examples and it remains an active area of research. The problem of stabilizing trajectories optimized offline remains a challenge, particularly when the execution deviates from the planned mode sequence. Computational requirements still prevent nonlinear trajectory optimization methods from being applied online as an MPC algorithm, but improvements in numerical solvers and computing hardware will likely continue to reduce this gap.

48.6.2 Orbital Trajectory Stabilization and Control

Once an open-loop gait is generated, it must typically be stabilized in order to be executed on a robot. Classical techniques for trajectory stabilization from linear control can work, but a strong theme in stabilization for legged robots has been the idea that one should not enforce the precise timing of the trajectory. Section 48.3.2 discussed the notion of orbital stability and introduced Poincaré maps as a tool for stability analysis. Orbital stabilization, rather than traditional trajectory stabilization, sacrifices little and appears to be more compatible with underactuated robots. These ideas have also played an important role in developing stable dynamic walking and running controllers using *virtual constraints* [48.38]. Virtual constraints are holonomic constraints on monotonic functions of the robot's configuration variables. For example, for a forward periodic gait, it might be reasonable to assume that the angle of the stance leg with respect to the ground θ_{st} is monotonically increasing in time throughout the stance phase. The remaining configuration variables are written as functions of θ_{st} , effectively reparametrizing time, and constraints are imposed that, e.g., enforce sym-

metry in stance and swing leg angles ($\theta_{sw} = -\theta_{st}$) or coordinate arm and leg motion. This leads to outputs

$$y = \begin{bmatrix} h_1(q) \\ \vdots \\ h_d(q) \end{bmatrix}, \quad (48.72)$$

where each $h_i(q)$ encodes a virtual constraint. For example, $h(q) = \theta_{sw} + \theta_{st}$ encodes the virtual constraint for swing-stance leg symmetry. By driving the output dynamics asymptotically to 0 using high-gain control, the system can be seen to evolve according to the virtual constraints, yielding a lower dimensional problem for control design and stability analysis. This approach has been used to produce remarkable dynamic walking and running examples in real robots [48.191].

Poincaré maps are defined with respect to a transverse surface at a single point on a periodic orbit, which limits their usefulness for designing stabilizing controllers. The *transverse dynamics*, on the other hand, is defined with respect to a *continuous* family of surfaces $S(t)$, transverse to the orbit [48.45]. In the neighborhood of these coordinates, the dynamics can be written as

$$\dot{\tau} = 1 + f_1(\tau, \mathbf{x}_\perp) \quad (48.73)$$

$$\dot{\mathbf{x}}_\perp = \mathbf{A}(\tau)\mathbf{x}_\perp + f_2(\tau, \mathbf{x}_\perp), \quad (48.74)$$

where $\tau \in [0, t_f]$ represents the orbit phase, \mathbf{x}_\perp are the $2N - 1$ coordinates orthogonal to the flow of the system, and $f_1(\cdot), f_2(\cdot)$ are functions containing nonlinear terms. Note that unlike the discrete Poincaré map, these dynamics do not require the trajectory of interest to be a periodic orbit.

By extracting the linear part of the transversal dynamics and incorporating control inputs, we obtain the transverse linearization

$$\dot{\mathbf{z}}(t) = \mathbf{A}(t)\mathbf{z}(t) + \mathbf{B}(t)\mathbf{u}(t), \quad (48.75)$$

for $t \in [0, t_f]$. Stabilization of this system, and therefore the underlying trajectory, can be approached using stan-

Fig. 48.11 A simple illustration of transverse linearization along a nominal trajectory (red) for systems with impacts

dard techniques from linear control theory. For walking systems with impulses, the dynamics can be extended to include a linearized impact map, $\mathbf{z}(t_i^+) = \mathbf{C}_i \mathbf{z}(t_i^-)$, where $t_i, i \in C$ are times at which impacts occur. Figure 48.11 illustrates the idea of transversal surfaces about a trajectory for a system with impacts. Manchester et al. [48.50] showed that under some mild assumptions, local exponential orbital stability of planned motions on a hybrid nonlinear system can be achieved using a receding horizon control with the transverse linear dynamics.

Minor variations in impact timing can be handled in linearization-based approaches to stabilizing walking trajectories, but perturbations that lead to changes in mode ordering often cannot. To address this problem, we need algorithms for adjusting walking trajectories online. As described in the previous section, the hybrid nature of walking systems makes this challenging. One way to avoid this issue is to employ smooth approximations of the dynamics that permit the use of efficient local trajectory optimization techniques at the expense of violating complementarity condition (48.22) by, e.g., allowing interpenetration of rigid bodies. This approach has led to impressive examples of online trajectory optimization for simulated systems [48.192], but it is yet unknown how well these approximations will transfer to physical systems.

48.7 Different Contact Behaviors

Contact forces have appeared throughout this chapter to be central for the modeling and control of legged robots. As a result, a different contact behavior can result in a significantly different dynamical behavior of the whole robot, and this can be extremely useful in situations where standard walking or running is inefficient or downright impossible.

48.7.1 Wall Climbing

Wall climbing legged robots rely on various devices such as suction cups, magnets, adhesive materials,

miniature spine arrays, that can generate adhesive forces in order to stick to various vertical surfaces such as glass, steel, concrete, brick, stone [48.193–195]. In this case, the unilaterality condition (48.11), which was central throughout this chapter, is no more relevant. As a result, the whole locomotion modeling and control is deeply transformed.

48.7.2 Tethered Walking

On steep slopes, rappelling is an interesting option, tethering the robot to anchors in order to avoid tumbling

down. This has been experienced successfully on construction sites [48.196], or in a volcano in the case of the impressive Carnegie Mellon University (CMU) Dante II octopod robot [48.197]. In this case, the locomotion problem is similar to the general case described throughout this chapter, but the tether introduces an additional contact between the robot and the environment, on which the robot can pull but not push, so a unilateral contact exactly opposite to the standard unilateral contact between the feet and the ground, what can be treated however in exactly the same way.

48.7.3 Legs with Wheels

Adapting wheeled vehicles to rough terrain has led in some cases to implant wheels on legs, combining the flexibility of articulated legs on rough terrain with the efficiency of wheels on flat terrain. Different options are possible, passive or active wheels, passive

or active legs [48.198–202]. In this case, the unilaterality condition (48.11) is fundamental like in the rest of this chapter, but the contact points can move freely on the contact surfaces along the direction of the wheels, what can significantly increase the array of possible motions [48.203]. Problems similar to those of standard legged robots include finding stable postures and allocating contact forces for maximizing stability and efficiency [48.200–202]. Interestingly, the case of passive wheels results in motions similar to skating [48.198].

48.7.4 Wheels with Legs

Evolving the mechanical design of legs for greater simplicity and improved efficiency has led in some cases to directly implant the legs on wheels [48.204, 205]. This results in very impressive outdoor performance, but not much related to standard legged robots in the end.

48.8 Conclusion

Legged systems are at the heart of some of the most exciting work in modern robotics. They offer the opportunity to travel to places beyond the reach of wheeled systems and gain fundamental insights into the conditions under which stable and efficient locomotion is possible. At the same time, their complex dynamics pose significant challenges for our computational approaches to control and stability analysis. Indeed, the simple fact that every walking system must engage in

intermittent contact with its environment has significant mathematical implications.

A large number of success stories for legged systems moving with remarkable precision and reliability have been witnessed over the past decade, and the development of exciting new tools for optimization-based planning, control, and analysis offers the promise to develop machines that achieve even higher levels of robustness and efficiency.

49. Modeling and Control of Wheeled Mobile Robots

Claude Samson, Pascal Morin, Roland Lenain

This chapter may be seen as a follow up to Chap. 24, devoted to the classification and modeling of basic wheeled mobile robot (WMR) structures, and a natural complement to Chap. 47, which surveys motion planning methods for WMRs. A typical output of these methods is a feasible (or admissible) reference state trajectory for a given mobile robot, and a question which then arises is how to make the physical mobile robot track this reference trajectory via the control of the actuators with which the vehicle is equipped. The object of the present chapter is to bring elements of the answer to this question based on simple and effective control strategies.

The chapter is organized as follows. Section 49.2 is devoted to the choice of control models and the determination of modeling equations associated with the path-following control problem. In Sect. 49.3, the path following and trajectory stabilization problems are addressed in the simplest case when no requirement is made on the robot orientation (i. e., position control). In Sect. 49.4 the same problems are revisited for the control of both position and orientation. The previously mentioned sections consider an ideal robot satisfying the rolling-without-sliding assumption. In Sect. 49.5, we relax this assumption in order to take into account nonideal wheel-ground contact. This is especially important for field-robotics applications and the proposed results are validated through full scale experiments on natural terrain. Finally, a few complementary issues on the feedback control of mobile robots are briefly discussed in the concluding Sect. 49.6, with a list of commented references for further reading on WMRs motion control.

49.1 Background

Wheeled mobile robotics remains a very active research topic, as witnessed by the Darpa Grand Challenges [49.1]. The first Grand Challenge, in 2005, took place in a clear environment and was won by Stanley (Fig. 49.1a). The second Grand Challenge, in 2007, took place in urban environment and demonstrated autonomous driving capabilities, especially in complex environments with strong safety and reliability issues. This made possible the development of autonomous cars, such as google car (Fig. 49.1b). Whatever the sensors used for localization and detection, the use in every day life of cybercars, such as VipaLab (Fig. 49.1c), is becoming a reality. Numerous tests are under progress all around the world showing the benefits of autonomous transportation systems. On-road transportation probably constitutes the main and most visible application domain of emerging autonomous wheeled robots. Driving assistance for human activities in off-road conditions constitutes another application domain. Indeed, WMRs can also be used in hazardous environments, or in environments that are not reachable by humans. Planetary exploration (Chap. 55), with the example of Curiosity (Fig. 49.1d), is a popular example of such applications. Other developments, concerning people well-being and safety, are also investigated in the field of environment monitoring, surveillance, agriculture, civil protection or defence. Figure 49.1e,f illustrate these developments with the first one representing the Claas etrion robot (for au-

tonomous farming, see also Chap. 56) and the second one representing the SUGV robot manufactured by iRobot. This robot, dedicated to civil protection, was the first one to enter the damaged Fukushima power plant. All these examples highlight the possible benefits and different applications of WMRs. The variety of robot designs (in term of scale, locomotion mode, or related actuation strategy see Chap. 24), is in line with the diversity of application needs. Whatever the system and application, however, autonomy relies on the design of efficient feedback laws that can ensure precise autonomous motion of the vehicle despite all possible modeling errors and perturbations. This chapter is dedicated to this issue and aims at providing the basics of feedback control design for nonholonomic WMRs. Implementation of these control laws supposes that one is able to measure the variables involved in the control loop (typically the position and orientation of the mobile robot with respect to either a fixed frame or a path that the vehicle should follow). Throughout this chapter we will assume that these measurements are available continuously in time and that they are not corrupted by noise. In a general manner, robustness considerations will not be discussed in detail, one reason being that, beyond imposed space limitations, a large part of the presented approaches are based on linear control theory. The feedback control laws then inherit the strong robustness properties associated with stable linear systems. Results can also be subsequently refined by using

complementary, eventually more elaborate, automatic control techniques. For the sake of simplicity, the control methods are developed mainly for unicycle-type and car-like mobile robots, which correspond respectively to the types (2, 0) and (1, 1) in the classification proposed in Chap. 24. Most of the results can in fact be easily extended/adapted to other mobile robots, in particular to systems with trailers. We will mention the cases where such extensions are straightforward. All reported simulation results, illustrating various control problems and solutions, are carried out for a car-like vehicle, whose kinematics is slightly more complex than that of unicycle-type vehicles.

Recall (Fig. 49.2) that:

1. A *unicycle-type mobile robot* is schematically composed of two independent actuated wheels on a common axle whose direction is rigidly linked to the robot chassis, and one or several passively orientable – or caster – wheels, which are not controlled and serve for sustentation purposes.
2. A (rear-drive) *car-like mobile robot* is composed of a motorized wheeled axle at the rear of the chassis, and one (or a pair of) orientable front steering wheel(s).

Note also, as illustrated by the diagram below (Fig. 49.3), that a car-like mobile robot can be viewed (at least kinematically) as a unicycle-type mobile robot to which a trailer is attached.

Despite the variety of application, three generic control problems can mainly be considered in mobile robotics and are detailed in this chapter.

49.1.1 Path Following

Given a curve C on the plane, a (nonzero) longitudinal velocity v_0 for the robot chassis, and a point P attached to the chassis, the goal is to have the point P follow the curve C when the robot moves with the velocity v_0 . The variable that one has to stabilize at zero is thus the distance between the point P and the curve (i.e., the distance between P and the closest point M on C). This type of problem typically corresponds to driving on a road while trying to maintain the distance between

Fig. 49.2a,b Unicycle-type (a) and car-like (b) mobile robots

the vehicle chassis and the side of the road constant. Automatic wall following is another possible application.

49.1.2 Stabilization of Trajectories

This problem differs from the previous one in that the vehicle's longitudinal velocity is no longer predetermined because one also aims to monitor the distance gone along the curve C . This objective supposes that the geometric curve C is complemented with a time schedule, i.e., that it is parameterized with the time variable t . This boils down to defining a trajectory $t \mapsto (x_r(t), y_r(t))$ with respect to a reference frame \mathcal{F}_0 . Then the goal is to stabilize the position error vector $(x(t) - x_r(t), y(t) - y_r(t))$ at zero, with $(x(t), y(t))$ denoting the coordinates of point P in \mathcal{F}_0 at time t . The problem may also be formulated as one of controlling the vehicle in order to track a reference vehicle whose trajectory is given by $t \mapsto (x_r(t), y_r(t))$. Note that perfect tracking is achievable only if the reference trajectory is feasible for the physical vehicle, and that a trajectory which is feasible for a unicycle-type vehicle is not necessarily feasible for a car-like vehicle. Also, in addition to monitoring the position $(x(t), y(t))$ of the robot, one may be willing to control the chassis orientation $\theta(t)$ at a desired reference value $\theta_r(t)$ associated with the orientation of the reference vehicle. For a nonholonomic unicycle-type robot, a reference trajectory $(x_r(t), y_r(t), \theta_r(t))$ is feasible if it is produced by a reference vehicle which has the same kinematic limitations as the physical robot. For instance, most trajectories produced by an omnidirectional vehicle (omnibible vehicle in the terminology of Chap. 24) are not feasible for a nonholonomic mobile robot. However, nonfeasibility does not imply that the reference trajectory cannot be tracked in an approximate manner, i.e., with small (although nonzero) tracking errors.

49.1.3 Stabilization of Fixed Postures

Let \mathcal{F}_1 denote a frame attached to the robot chassis. In this chapter, we call a robot posture (or situation) the association of the position of a point P located on the robot chassis with the orientation $\theta(t)$ of \mathcal{F}_1 with respect to a fixed frame \mathcal{F}_0 in the plane of motion. For

Fig. 49.3 Analogy car/unicycle with trailer

this last problem, the objective is to stabilize at zero the posture vector $\xi(t) = (x(t), y(t), \theta(t))$, with $(x(t), y(t))$ denoting the position of P expressed in \mathcal{F}_0 . Although

a fixed desired (or reference) posture is obviously a particular case of a feasible trajectory, this problem cannot be solved by classical control methods.

49.2 Control Models

49.2.1 Kinematics Versus Dynamics

In order to proceed with the control of mobile robots, a model describing its motion has to be derived. Several levels of motion equations may be derived, pending on the targeted application (expected velocity, terrain configuration, etc.). Chapter 24 provides a general configuration dynamic model for WMRs. Its particularization to the case of unicycle-type and car-like mobile robots gives

$$\mathbf{H}(\mathbf{q})\dot{\mathbf{u}} + \mathbf{F}(\mathbf{q}, \mathbf{u})\mathbf{u} = \mathbf{\Gamma}(\phi)\boldsymbol{\tau} , \quad (49.1)$$

with \mathbf{q} denoting a robot's configuration vector, \mathbf{u} a vector of independent velocity variables associated with the robot's degrees of freedom, $\mathbf{H}(\mathbf{q})$ a reduced inertia matrix (which is invertible for any \mathbf{q}), $\mathbf{F}(\mathbf{q}, \mathbf{u})\mathbf{u}$ a vector of forces combining the contribution of Coriolis and wheel-ground contact forces, ϕ the orientation angle of the car's steering wheel, $\mathbf{\Gamma}$ an invertible control matrix (which is constant in the case of a unicycle-type vehicle), and $\boldsymbol{\tau}$ a vector of independent motor torques (whose dimension is equal to the number of degrees of freedom in the case of full actuation, i.e., equal to two for the vehicles considered herein). In the case of a unicycle-type vehicle, a configuration vector is composed of the components of the chassis posture vector ξ and the orientation angles of the castor wheels (with respect to the chassis). In the case of a car-like vehicle, a configuration vector is composed of the components of ξ and the steering wheel angle ϕ . To be complete, this dynamic model must be complemented with kinematic equations in the form

$$\dot{\mathbf{q}} = \mathbf{S}(\mathbf{q})\mathbf{u} , \quad (49.2)$$

from which one can extract a reduced kinematic model

$$\dot{\mathbf{z}} = \mathbf{B}(\mathbf{z})\mathbf{u} , \quad (49.3)$$

with $\mathbf{z} = \xi$, in the case of a unicycle-type vehicle, and $\mathbf{z} = (\xi, \phi)$ in the case of a car-like vehicle. In the automatic control terminology, the complete dynamic

model (49.1) and (49.2) forms a *control system* which can be written as

$$\dot{\mathbf{X}} = \mathbf{f}(\mathbf{X}, \boldsymbol{\tau}) \quad \text{with} \quad \mathbf{X} = (\mathbf{q}, \mathbf{u})$$

denoting the state vector of this system, and $\boldsymbol{\tau}$ the vector of control inputs. The kinematic models (49.2) and (49.3) are also control systems with respective state vectors \mathbf{q} and \mathbf{z} and control vector \mathbf{u} . Any of these models can be used for control design and analysis purposes. In the remainder of this chapter, we have chosen to work with the kinematic model (49.3). By analogy with the motion control of manipulator arms, this boils down to using a model with velocity control inputs, rather than a model with torque control inputs. This is justified when dynamic effects are not preponderant and low-level velocity control loops on the wheels motor are powerful enough to ensure good velocity tracking. In Sect. 49.5, however, when nonideal wheel-ground contact is addressed, dynamics is considered.

49.2.2 Modeling in an Absolute Frame

For the unicycle-type mobile robot, the kinematic model (49.3) used from now on is

$$\begin{cases} \dot{x} = u_1 \cos \theta , \\ \dot{y} = u_1 \sin \theta , \\ \dot{\theta} = u_2 , \end{cases} \quad (49.4)$$

where (x, y) represents the coordinates of the point P_m located at mid-distance of the actuated wheels, and the angle θ characterizes the robot's chassis orientation (Fig. 49.4). In this equation, u_1 represents the intensity of the vehicle's longitudinal velocity, and u_2 is the chassis instantaneous velocity of rotation. The variables u_1 and u_2 are themselves related to the angular velocity of the actuated wheels via the one-to-one relations

$$\begin{aligned} u_1 &= \frac{r}{2}(\dot{\psi}_r + \dot{\psi}_\ell) , \\ u_2 &= \frac{r}{2R}(\dot{\psi}_r - \dot{\psi}_\ell) , \end{aligned}$$

with r the wheels' radius, R the distance between the two actuated wheels, and $\dot{\psi}_r$ (resp. $\dot{\psi}_\ell$) the angular velocity of the right (resp. left) rear wheel.

For the car-like mobile robot, the kinematic model (49.3) used from now on is

$$\begin{cases} \dot{x} = u_1 \cos \theta, \\ \dot{y} = u_1 \sin \theta, \\ \dot{\theta} = \frac{u_1}{L} \tan \phi, \\ \dot{\phi} = u_2, \end{cases} \quad (49.5)$$

where ϕ represents the vehicle's steering wheel angle, and L is the distance between the rear and front wheels' axes. In all forthcoming simulations, L is set equal to 1.2 m.

49.2.3 Modeling in a Frénet Frame

The object of this subsection is to generalize the previous kinematic equations when the reference frame is a Frénet frame. This generalization will be used later on when addressing the path following problem.

Let us consider a curve C in the plane of motion, as illustrated on Fig. 49.5, and let us define three frames \mathcal{F}_0 , \mathcal{F}_m , and \mathcal{F}_s , as follows. $\mathcal{F}_0 = \{0, \mathbf{i}, \mathbf{j}\}$ is a fixed frame, $\mathcal{F}_m = \{P_m, \mathbf{i}_m, \mathbf{j}_m\}$ is a frame attached to the mobile robot with its origin – the point P_m – located on the rear wheels axle, at the mid-distance of the wheels, and $\mathcal{F}_s = \{P_s, \mathbf{i}_s, \mathbf{j}_s\}$, which is indexed by the curve's curvilinear abscissa s , is such that the unit vector \mathbf{i}_s tangents C . Consider now a point P attached to the robot chassis, and let (l_1, l_2) denote the coordinates of P expressed in the basis of \mathcal{F}_m . To determine the equations of motion of P with respect to the curve C let us introduce three variables s , d , and θ_e , defined as follows:

- s is the curvilinear abscissa at the point P_s obtained by projecting P orthogonally on C . This point exists and is unique if the point P is close enough to the curve. More precisely, it suffices that the distance between P and the curve be smaller than the lower bound of the curve radii. We will assume that this condition is satisfied.
- d is the ordinate of P in the frame \mathcal{F}_s ; its absolute value is also the distance between P and the curve.
- $\theta_e = \theta - \theta_s$ is the angle characterizing the orientation of the robot chassis with respect to the frame \mathcal{F}_s .

We also define the curvature $c(s)$ of C at P_s , i.e., $c(s) = \partial \theta_s / \partial s$.

Fig. 49.4 Configuration variables

Fig. 49.5 Representation in a Frénet frame

Using these notations one easily deduces from (49.4) the following system of equations ([49.2] for details), which generalizes (49.4)

$$\begin{cases} \dot{s} = \frac{1}{1-dc(s)} [(u_1 - l_2 u_2) \cos \theta_e - l_1 u_2 \sin \theta_e], \\ \dot{d} = (u_1 - l_2 u_2) \sin \theta_e + l_1 u_2 \cos \theta_e, \\ \dot{\theta}_e = u_2 - \dot{s} c(s). \end{cases} \quad (49.6)$$

For car-like vehicles, one easily verifies, by using (49.5), that the system (49.6) becomes

$$\begin{cases} \dot{s} = \frac{u_1}{1-dc(s)} \left[\cos \theta_e - \frac{\tan \phi}{L} (l_2 \cos \theta_e + l_1 \sin \theta_e) \right], \\ \dot{d} = u_1 \left[\sin \theta_e + \frac{\tan \phi}{L} (l_1 \cos \theta_e - l_2 \sin \theta_e) \right], \\ \dot{\theta}_e = \frac{u_1}{L} \tan \phi - \dot{s} c(s), \\ \dot{\phi} = u_2. \end{cases} \quad (49.7)$$

49.3 Adaptation of Control Methods for Holonomic Systems

We address in this section the problems of trajectory stabilization and path following. When we defined these problems in the introduction, we considered a reference point P attached to the robot chassis. It turns out that the choice of this point is important. Indeed, consider for instance the equations (49.6) for a unicycle point P when C is the axis (O, i) . Then, $s = x_P$, $d = y_P$, and $\theta_e = \theta$ represent the robot's posture with respect to the fixed reference frame \mathcal{F}_0 . There are two possible cases depending on whether P is, or is not, located on the actuated wheels axle. Let us consider the first case, for which $l_1 = 0$. From the first two equations of (49.6), one has

$$\dot{x}_P = (u_1 - l_2 u_2) \cos \theta, \quad \dot{y}_P = (u_1 - l_2 u_2) \sin \theta.$$

These relations indicate that P can move only in the direction of the vector $(\cos \theta, \sin \theta)$. This is a direct consequence of the nonholonomy constraint to which the vehicle is subjected. Now, if P is not located on the wheels axle, then

$$\begin{pmatrix} \dot{x}_P \\ \dot{y}_P \end{pmatrix} = \begin{pmatrix} \cos \theta & -l_1 \sin \theta \\ \sin \theta & l_1 \cos \theta \end{pmatrix} \begin{pmatrix} 1 & -l_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}. \quad (49.8)$$

The fact that the two square matrices in the right-hand side of this equality are invertible indicates that \dot{x}_P and \dot{y}_P can take any values, and thus that the motion of P is not constrained. By analogy with holonomic manipulator arms, this means that P may be seen as the extremity of a two-degree-of-freedom (2-DOF) manipulator, and thus that it can be controlled by applying the same control laws as those used for manipulators. In this section, we assume that the point P , used to characterize the robot's position, is chosen away from the rear wheels axle. In this case we will see that the problems of trajectory stabilization and path following can be solved very simply. However, as shown in the subsequent section, choosing P on the wheels axle may also be of interest in order to better control the vehicle's orientation.

49.3.1 Stabilization of Trajectories for a Nonconstrained Point

Unicycle

Consider a differentiable reference trajectory $t \mapsto (x_r(t), y_r(t))$ in the plane. Let $e = (x_P - x_r, y_P - y_r)$ denote the tracking error in position. The control objective is to asymptotically stabilize this error at zero. In view

of (49.8), the error equations are

$$\dot{e} = \begin{pmatrix} \cos \theta & -l_1 \sin \theta \\ \sin \theta & l_1 \cos \theta \end{pmatrix} \begin{pmatrix} u_1 - l_2 u_2 \\ u_2 \end{pmatrix} - \begin{pmatrix} \dot{x}_r \\ \dot{y}_r \end{pmatrix}. \quad (49.9)$$

Introducing new control variables (v_1, v_2) defined by

$$\begin{pmatrix} v_1 \\ v_2 \end{pmatrix} = \begin{pmatrix} \cos \theta & -l_1 \sin \theta \\ \sin \theta & l_1 \cos \theta \end{pmatrix} \begin{pmatrix} u_1 - l_2 u_2 \\ u_2 \end{pmatrix}, \quad (49.10)$$

the equations (49.9) become simply

$$\dot{e} = \begin{pmatrix} v_1 \\ v_2 \end{pmatrix} - \begin{pmatrix} \dot{x}_r \\ \dot{y}_r \end{pmatrix}.$$

The classical techniques of stabilization for linear systems can then be used. For instance, one may consider a proportional feedback control with precompensation such as

$$\begin{aligned} v_1 &= \dot{x}_r - k_1 e_1 = \dot{x}_r - k_1 (x_P - x_r), & (k_1 > 0), \\ v_2 &= \dot{y}_r - k_2 e_2 = \dot{y}_r - k_2 (y_P - y_r), & (k_2 > 0), \end{aligned}$$

which yields the closed-loop equation $\dot{e} = -Ke$. Of course, this control can be rewritten for the initial control variables u , since the mapping $(u_1, u_2) \mapsto (v_1, v_2)$ is bijective.

Car

This technique extends to car-like vehicles (and also to trailer systems) by choosing a point P attached to the steering wheel frame and not located on the steering wheel axle.

49.3.2 Path Following with no Orientation Control

Unicycle

Let us adopt the notation of Fig. 49.5 to address the problem of following a path associated with a curve C in the plane. The control objective is to stabilize the distance d at zero. From (49.6), one has

$$\dot{d} = u_1 \sin \theta_e + u_2 (-l_2 \sin \theta_e + l_1 \cos \theta_e). \quad (49.11)$$

Recall that in this case the vehicle's longitudinal velocity u_1 is either imposed or prespecified. We will assume that the product $l_1 u_1$ is positive, i. e., the position of the point P with respect to the actuated wheels axle is chosen in relation to the sign of u_1 . This assumption will

be removed in Sect. 49.4. To simplify, we will also assume that $l_2 = 0$, i. e., the point P is located on the axis (P_m, i_m) . Let us then consider the following feedback control law

$$u_2 = -\frac{u_1 \tan \theta_e}{l_1} - \frac{u_1}{\cos \theta_e} k(d, \theta_e) d, \quad (49.12)$$

with k a continuous, strictly positive, function on $\mathbb{R} \times (-\pi/2, \pi/2)$ such that $k(d, \pm\pi/2) = 0$. Since $l_2 = 0$, applying the control (49.12) to (49.11) gives

$$\dot{d} = -l_1 u_1 k(d, \theta_e) d,$$

which suggests that the control law (49.12) ensures convergence of d to zero under adequate conditions on l_1 , u_1 , and k . This is made precise in the following result ([49.2] for details).

Proposition 49.1

Consider the path following problem for a unicycle-type mobile robot with

- A. A strictly positive, or strictly negative, longitudinal velocity u_1 .

- B. A reference point P of coordinates $(l_1, 0)$ in the vehicle's chassis frame, with $l_1 u_1 > 0$.

Let k denote a continuous function, strictly positive on $\mathbb{R} \times (-\pi/2, \pi/2)$, and such that $k(d, \pm\pi/2) = 0$ for every d (for instance, $k(d, \theta_e) = k_0 \cos \theta_e$). Then, for any initial conditions $(s(0), d(0), \theta_e(0))$ such that

$$\theta_e(0) \in (-\pi/2, \pi/2), \quad \frac{l_1 c_{\max}}{1 - |d(0)| c_{\max}} < 1,$$

with $c_{\max} = \max_s |c(s)|$, the feedback control (49.12) makes the distance $|d|$ between P and the curve non-increasing, and makes it converge to zero if

$$\int_0^t |u_1(s)| ds \rightarrow +\infty \quad \text{when } t \rightarrow +\infty.$$

Car

This control technique also applies to car (or trailer systems) by considering a point P attached to the steering wheel frame, with u_1 positive.

49.4 Methods Specific to Nonholonomic Systems

The control methods recalled in the previous section are simple and sufficient for many applications. Their main limitation comes from the fact that the robot's orientation is not actively controlled. This becomes a problem when the application requires manoeuvres (i. e., when the vehicle's velocity u_1 has to become negative). This issue is especially critical for trailer systems (including car-like vehicles). Indeed, when the longitudinal velocity is positive, the leader vehicle has a *pulling* action which tends to align the followers along the curve. In the other case, the leader has a *pushing* action which tends to misalign them, thus leading to collisions be-

tween the vehicles' components (the jackknife effect, see Fig. 49.6 for illustration). In order to remove this constraint on the sign of the longitudinal velocity, the control has to be designed so that all orientation angles are actively stabilized. An indirect way to do this consists in choosing the point P on the actuated wheels axle, at the mid-distance of the wheels, for instance. In this case, the nonholonomy constraints intervene much more explicitly, and the control can no longer be obtained by applying the techniques used for holonomic manipulators.

This section is organized as follows. First, the modeling equations with respect to a Frénet frame are recast into a canonical form called the chained form. From there, a solution to the path-following problem with active stabilization of the vehicle's orientation is worked out. The problem of (feasible) trajectory stabilization is also revisited with the complementary objective of controlling the vehicle's orientation. The asymptotic stabilization of fixed postures is then addressed. Finally, some comments on the limitations of the proposed control strategies, in relation to the objective of asymptotic stabilization, serve to motivate and introduce a new control approach developed in the subsequent section.

Fig. 49.6 Path-following instability with reverse longitudinal velocity

49.4.1 Transformation of Kinematic Models into the Chained Form

The chapter dedicated to path planning shows how the kinematic equations of the mobile robots here considered (unicycle-type, car-like, with trailers) can be transformed into the chain form via a change of state and control variables. In particular, the equations of a unicycle (49.4), and those of a car (49.5), can be transformed into a three-dimensional and a four-dimensional chained system, respectively. Those of a unicycle-type vehicle with N trailers yield a chained system of dimension $N + 3$ when the trailers are hooked to each other in a specific way. As shown below, this transformation can be generalized to the kinematic models derived with respect to a Frénet frame. The result will be given only for the unicycle and car cases (49.6) and (49.7), but it also holds for trailer systems. The reference point P is now chosen at the mid-distance of the vehicle's rear wheels (or at the mid-distance of the wheels of the last trailer, when trailers are involved).

Let us start with the unicycle case. Under the assumption that P corresponds to the origin of \mathcal{F}_m , one has $l_1 = l_2 = 0$ so that the system (49.6) simplifies to

$$\begin{cases} \dot{s} = \frac{u_1}{1 - dc(s)} \cos \theta_e, \\ \dot{d} = u_1 \sin \theta_e, \\ \dot{\theta}_e = u_2 - \dot{s}c(s). \end{cases} \quad (49.13)$$

Let us determine a change of coordinates and control variables $(s, d, \theta_e, u_1, u_2) \mapsto (z_1, z_2, z_3, v_1, v_2)$ allowing to (locally) transform (49.13) into the three-dimensional chained system

$$\begin{cases} \dot{z}_1 = v_1, \\ \dot{z}_2 = v_1 z_3, \\ \dot{z}_3 = v_2. \end{cases} \quad (49.14)$$

By first setting

$$z_1 = s, \quad v_1 = \dot{s} = \frac{u_1}{1 - dc(s)} \cos \theta_e,$$

we already obtain $\dot{z}_1 = v_1$. This implies that

$$\begin{aligned} \dot{d} &= u_1 \sin \theta_e = \frac{u_1}{1 - dc(s)} \cos \theta_e [1 - dc(s)] \tan \theta_e \\ &= v_1 [1 - dc(s)] \tan \theta_e. \end{aligned}$$

We then set $z_2 = d$ and $z_3 = [1 - dc(s)] \tan \theta_e$, so that the above equation becomes $\dot{z}_2 = v_1 z_3$. Finally, we define

$$\begin{aligned} v_2 &= \dot{z}_3 \\ &= \left[-\dot{dc}(s) - d \frac{\partial c}{\partial s} \dot{s} \right] \tan \theta_e \\ &\quad + [1 - dc(s)] (1 + \tan^2 \theta_e) \dot{\theta}_e. \end{aligned}$$

The equations (49.14) are satisfied with the variables z_i and v_i so defined.

From this construction it is simple to verify that the mapping $(s, d, \theta_e) \mapsto z$ is a *local* change of coordinates defined on $\mathbb{R}^2 \times (-\pi/2, \pi/2)$ (to be more rigorous, one should also take the constraint $|d| < 1/c(s)$ into account). Let us finally remark that the change of control variables involves the derivative $(\partial c / \partial s)$ of the path's curvature (whose knowledge is thus needed for the calculations). In summary, we have shown that the change of coordinates and of control variables $(s, d, \theta_e, u_1, u_2) \mapsto (z_1, z_2, z_3, v_1, v_2)$ defined by

$$\begin{aligned} (z_1, z_2, z_3) &= (s, d, [1 - dc(s)] \tan \theta_e) \\ (v_1, v_2) &= (\dot{z}_1, \dot{z}_3) \end{aligned}$$

transforms the model (49.13) of a unicycle-type vehicle into a three-dimensional (3-D) chained system. One can similarly transform the car's equations into a four-dimensional (4-D) chained system, although the calculations are slightly more cumbersome. More precisely, the change of coordinates and control variables $(s, d, \theta_e, \phi, u_1, u_2) \mapsto (z_1, z_2, z_3, z_4, v_1, v_2)$ defined by

$$\begin{aligned} (z_1, z_2, z_3, z_4) &= \left\{ s, d, [1 - dc(s)] \tan \theta_e, \right. \\ &\quad \left. -c(s)[1 - dc(s)] (1 + 2 \tan^2 \theta_e) \right. \\ &\quad \left. - d \frac{\partial c}{\partial s} \tan \theta_e \right. \\ &\quad \left. + [1 - dc(s)]^2 \frac{\tan \phi}{L} \frac{1 + \tan^2 \theta_e}{\cos \theta_e} \right\}, \\ (v_1, v_2) &= (\dot{z}_1, \dot{z}_4) \end{aligned}$$

transforms the model (49.7) of a car-like vehicle (with $l_1 = l_2 = 0$) into a four-dimensional chained system.

49.4.2 Tracking of a Reference Vehicle with the Same Kinematics

Let us first consider the problem of tracking, in both position and orientation, a reference vehicle (Fig. 49.7). For simplicity, we choose P as the origin P_m of the robot's chassis frame \mathcal{F}_m .

Although the terminology is rather loose, the *tracking problem* is usually associated, in the control literature, with the problem of *asymptotically stabilizing* the reference trajectory. In this case, a necessary condition for the existence of a control solution is that the reference is feasible. Feasible trajectories $t \mapsto (x_r(t), y_r(t), \theta_r(t))$ are smooth time functions which are solution to the robot's kinematic model for some specific control input $t \mapsto \mathbf{u}_r(t) = (u_{1,r}(t), u_{2,r}(t))^T$, called the *reference control*. For a unicycle-type robot for example, this means in view of (49.4) that

$$\begin{cases} \dot{x}_r = u_{1,r} \cos \theta_r, \\ \dot{y}_r = u_{1,r} \sin \theta_r, \\ \dot{\theta}_r = u_{2,r}. \end{cases} \quad (49.15)$$

In other words, feasible reference trajectories correspond to the motion of a reference frame $\mathcal{F}_r = \{\mathbf{P}_r, \mathbf{i}_r, \mathbf{j}_r\}$ rigidly attached to a reference unicycle-type robot, with \mathbf{P}_r (alike $\mathbf{P} = \mathbf{P}_m$) located at the mid-distance of the actuated wheels (Fig. 49.7). From there, the problem is to determine a feedback control which asymptotically stabilizes the tracking error $(x - x_r, y - y_r, \theta - \theta_r)$ at zero, with (x_r, y_r) being the coordinates of \mathbf{P}_r in \mathcal{F}_0 , and θ_r the oriented angles between \mathbf{i} and \mathbf{i}_r . One can proceed as in the path-following case, first by establishing the error equations with respect to the frame \mathcal{F}_r , then by transforming these equations into the chain form via a change of variables like the one used to transform the kinematic equations of a mobile robot into a chained system, and finally by designing stabilizing control laws for the transformed system.

Expressing the tracking error in position $(x - x_r, y - y_r)$ with respect to the frame \mathcal{F}_r gives the vector (Fig. 49.7)

$$\begin{pmatrix} x_e \\ y_e \end{pmatrix} = \begin{pmatrix} \cos \theta_r & \sin \theta_r \\ -\sin \theta_r & \cos \theta_r \end{pmatrix} \begin{pmatrix} x - x_r \\ y - y_r \end{pmatrix}. \quad (49.16)$$

Calculating the time derivative of this vector yields

$$\begin{pmatrix} \dot{x}_e \\ \dot{y}_e \end{pmatrix} = \begin{pmatrix} u_{2,r} y_e + u_1 \cos(\theta - \theta_r) - u_{1,r} \\ -u_{2,r} x_e + u_1 \sin(\theta - \theta_r) \end{pmatrix}.$$

Fig. 49.7 Reference vehicle and error coordinates

By denoting $\theta_e = \theta - \theta_r$, the orientation error between the frames \mathcal{F}_m and \mathcal{F}_r , we obtain

$$\begin{cases} \dot{x}_e = u_{2,r} y_e + u_1 \cos \theta_e - u_{1,r}, \\ \dot{y}_e = -u_{2,r} x_e + u_1 \sin \theta_e, \\ \dot{\theta}_e = u_2 - u_{2,r}. \end{cases} \quad (49.17)$$

To determine a control (u_1, u_2) which asymptotically stabilizes the error (x_e, y_e, θ_e) at zero, let us consider the following change of coordinates and control variables

$$(x_e, y_e, \theta_e, u_1, u_2) \mapsto (z_1, z_2, z_3, w_1, w_2),$$

defined by

$$\begin{aligned} z_1 &= x_e, \\ z_2 &= y_e, \\ z_3 &= \tan \theta_e, \\ w_1 &= u_1 \cos \theta_e - u_{1,r}, \\ w_2 &= \frac{u_2 - u_{2,r}}{\cos^2 \theta_e}. \end{aligned} \quad (49.18)$$

Note that, around zero, this mapping is only defined when $\theta_e \in (-\pi/2, \pi/2)$. In other words, the orientation error between the physical robot and the reference robot has to be smaller than $\pi/2$.

It is immediate to verify that, in the new variables, the system (49.17) can be written as

$$\begin{cases} \dot{z}_1 = u_{2,r} z_2 + w_1, \\ \dot{z}_2 = -u_{2,r} z_1 + u_{1,r} z_3 + w_1 z_3, \\ \dot{z}_3 = w_2. \end{cases} \quad (49.19)$$

We remark that the last term in each of the above three equations corresponds to the one of a chained system. From here, it can be shown that the feedback control law

$$\begin{cases} w_1 = -k_1 |u_{1,r}| (z_1 + z_2 z_3) \quad (k_1 > 0), \\ w_2 = -k_2 u_{1,r} z_2 - k_3 |u_{1,r}| z_3, \quad (k_2, k_3 > 0), \end{cases} \quad (49.20)$$

makes the origin of system (49.19) globally asymptotically stable provided essentially that $u_{1,r}$ does not tend to zero as t tends to infinity. A precise stability statement and associated proof are provided in [49.2], together with complementary details about the gain tuning. Finally, the velocity control inputs u_1 and u_2 can be deduced from w_1 and w_2 by using the two last lines of (49.18).

Generalization to a Car-Like Vehicle

The previous method extends to the car case. We provide below the main steps of this extension. Consider the car's kinematic model (49.5) and a reference vehicle satisfying the same kinematic equations with all variables indexed by the subscript r . We assume that there exists $\delta \in (0, \pi/2)$ such that the reference steering angle ϕ_r belongs to the interval $[-\delta, \delta]$. By defining x_e , y_e , and θ_e as in the unicycle case, and by setting $\phi_e = \phi - \phi_r$, one obtains the following system

$$\begin{cases} \dot{x}_e = \left(\frac{u_{1,r}}{L} \tan \phi_r\right) y_e + u_1 \cos \theta_e - u_{1,r} , \\ \dot{y}_e = -\left(\frac{u_{1,r}}{L} \tan \phi_r\right) x_e + u_1 \sin \theta_e , \\ \dot{\theta}_e = \frac{u_1}{L} \tan \phi - \frac{u_{1,r}}{L} \tan \phi_r , \\ \dot{\phi}_e = u_2 - u_{2,r} . \end{cases} \quad (49.21)$$

Let us introduce the following new state variables

$$\begin{cases} z_1 = x_e , \\ z_2 = y_e , \\ z_3 = \tan \theta_e , \\ z_4 = \frac{\tan \phi - \cos \theta_e \tan \phi_r}{L \cos^3 \theta_e} + k_2 y_e , (k_2 > 0) . \end{cases}$$

We note that for any $\phi_r \in (-\pi/2, \pi/2)$, the mapping $(x_e, y_e, \theta_e, \phi) \mapsto z$ defines a diffeomorphism between $\mathbb{R}^2 \times (-\pi/2, \pi/2)^2$ and \mathbb{R}^4 . Introduce now the new control variables

$$\begin{cases} w_1 = u_1 \cos \theta_e - u_{1,r} , \\ w_2 = \dot{z}_4 = k_2 \dot{y}_e + \left(\frac{3 \tan \phi}{\cos \theta_e} - 2 \tan \phi_r\right) \frac{\sin \theta_e}{L \cos^3 \theta_e} \dot{\theta}_e \\ \quad - \frac{u_{2,r}}{L \cos^2 \phi_r \cos^2 \theta_e} + \frac{u_2}{L \cos^2 \phi \cos^3 \theta_e} . \end{cases} \quad (49.22)$$

One shows that $(u_1, u_2) \mapsto (w_1, w_2)$ defines a change of variables for θ_e , ϕ , and ϕ_r , inside the interval $(-\pi/2, \pi/2)$. These changes of state and control variables transform the system (49.21) into

$$\begin{cases} \dot{z}_1 = \left(\frac{u_{1,r}}{L} \tan \phi_r\right) z_2 + w_1 , \\ \dot{z}_2 = -\left(\frac{u_{1,r}}{L} \tan \phi_r\right) z_1 + u_{1,r} z_3 + w_1 z_3 , \\ \dot{z}_3 = -k_2 u_{1,r} z_2 + u_{1,r} z_4 \\ \quad + w_1 \left[z_4 - k_2 z_2 + (1 + z_3^2) \frac{\tan \phi_r}{L} \right] , \\ \dot{z}_4 = w_2 . \end{cases} \quad (49.23)$$

From here, one can deduce that the control law w_1 and w_2 defined as

$$\begin{cases} w_1 = -k_1 |u_{1,r}| \\ \quad \times \left\{ z_1 + \frac{z_3}{k_2} \left[z_4 + (1 + z_3^2) \frac{\tan \phi_r}{L} \right] \right\} , \\ w_2 = -k_3 u_{1,r} z_3 - k_4 |u_{1,r}| z_4 , \end{cases} \quad (49.24)$$

with $k_{1,2,3,4}$ denoting positive numbers, makes the origin of system (49.23) globally asymptotically stable provided essentially that $u_{1,r}$ does not tend to zero as t tends to infinity.

Simulation Results

The simulation shown on Fig. 49.8 and  VIDEO 181 illustrates this control scheme. The gain parameters k_i have been chosen as $(k_1, k_2, k_3, k_4) = (1, 1, 3, 3)$. The initial configuration of the reference vehicle (i.e., at $t = 0$), which is represented in Fig. 49.8a by dashed lines, is $(x_r, y_r, \theta_r)(0) = (0, 0, 0)$. The reference control u_r is defined by (49.25). The initial configuration of the controlled robot, represented in the figure by plain lines, is $(x, y, \theta)(0) = (0, -1.5, 0)$. The configurations at time $t = 10, 20$, and 30 , are also represented on the figure. Due to the fast convergence of the tracking error to zero (see the time evolution of the components x_e, y_e, θ_e of the tracking error in Fig. 49.8b), one can basically consider that the configurations of both vehicles coincide after time $t = 10$.

$$u_r(t) = \begin{cases} (1, 0)^T , & \text{if } t \in [0, 10] , \\ \{-1, 0.5 \cos[2\pi(t-10)/5]\}^T , & \text{if } t \in [10, 20] , \\ (1, 0)^T , & \text{if } t \in [20, 30] . \end{cases} \quad (49.25)$$

49.4.3 Path Following with Orientation Control

We reconsider the path-following problem with the reference point P now located on the actuated wheels axle, at the mid-distance of the wheels. The objective is to synthesize a control law which allows the vehicle to follow the path in a stable manner, independently of the sign of the longitudinal velocity.

Unicycle Case

We have seen in Sect. 49.4.1 how to transform kinematic equations with respect to a Frénet frame into the

three-dimensional chained system

$$\begin{cases} \dot{z}_1 = v_1, \\ \dot{z}_2 = v_1 z_3, \\ \dot{z}_3 = v_2. \end{cases} \quad (49.26)$$

Recall that $(z_1, z_2, z_3) = (s, d, (1 - dc(s)) \tan \theta_e)$ and that $v_1 = u_1 / (1 - dc(s)) \cos \theta_e$. The objective is to determine a control law which asymptotically stabilizes ($d = 0, \theta_e = 0$) and also ensures that the constraint on the distance d to the path (i.e., $|dc(s)| < 1$) is satisfied along the trajectories of the controlled system. For the control law, a first possibility consists in considering a proportional feedback like

$$v_2 = -v_1 k_2 z_2 - |v_1| k_3 z_3, \quad (k_2, k_3 > 0). \quad (49.27)$$

It is straightforward to verify that the origin of the closed-loop subsystem

$$\begin{cases} \dot{z}_2 = v_1 z_3, \\ \dot{z}_3 = -v_1 k_2 z_2 - |v_1| k_3 z_3 \end{cases} \quad (49.28)$$

is asymptotically stable when v_1 is constant, either positive or negative. Since u_1 (not v_1) is the intensity of the vehicle's longitudinal velocity, one would rather establish stability conditions which depend on u_1 . As detailed in [49.2], the control law (49.27) in fact makes the origin of system (49.28) asymptotically stable under the main condition that u_1 does not tend to zero as t tends to infinity. Note that the sign of u_1 now does not need to be constant. As for the constraint $|dc(s)| < 1$, it is satisfied along any solution to the controlled system provided that

$$z_2^2(0) + \frac{1}{k_2} z_3^2(0) < \frac{1}{c_{\max}^2},$$

with $c_{\max} = \max_s |c(s)|$.

From a practical point of view it can be useful to complement the control action with an integral term. More precisely, let us define a variable z_0 by $\dot{z}_0 = v_1 z_2$ with $z_0(0) = 0$. The control (49.27) can be modified as follows

$$\begin{aligned} v_2 &= -|v_1| k_0 z_0 - v_1 k_2 z_2 - |v_1| k_3 z_3, \\ &= -|v_1| k_0 \int_0^t v_1 z_2 - v_1 k_2 z_2 - |v_1| k_3 z_3, \\ &\quad (k_0, k_2, k_3 > 0, k_0 < k_2 k_3) \end{aligned} \quad (49.29)$$

leading to similar stability results as before. The constraint $|dc(s)| < 1$ is now satisfied along any solution to

the controlled system provided that

$$z_2^2(0) + \frac{1}{k_2 - \frac{k_0}{k_3}} z_3^2(0) < \frac{1}{c_{\max}^2}.$$

Generalization

One of the assets of this type of approach, besides the simplicity of the control law and little demanding conditions of stability associated with it, is that it can be generalized in a straightforward manner to car-like vehicles and unicycle-type vehicles with trailers. The result is summarized hereafter by considering an n -dimensional chained system

$$\begin{cases} \dot{z}_1 = v_1, \\ \dot{z}_2 = v_1 z_3, \\ \vdots \\ \dot{z}_{n-1} = v_1 z_n, \\ \dot{z}_n = v_2, \end{cases} \quad (49.30)$$

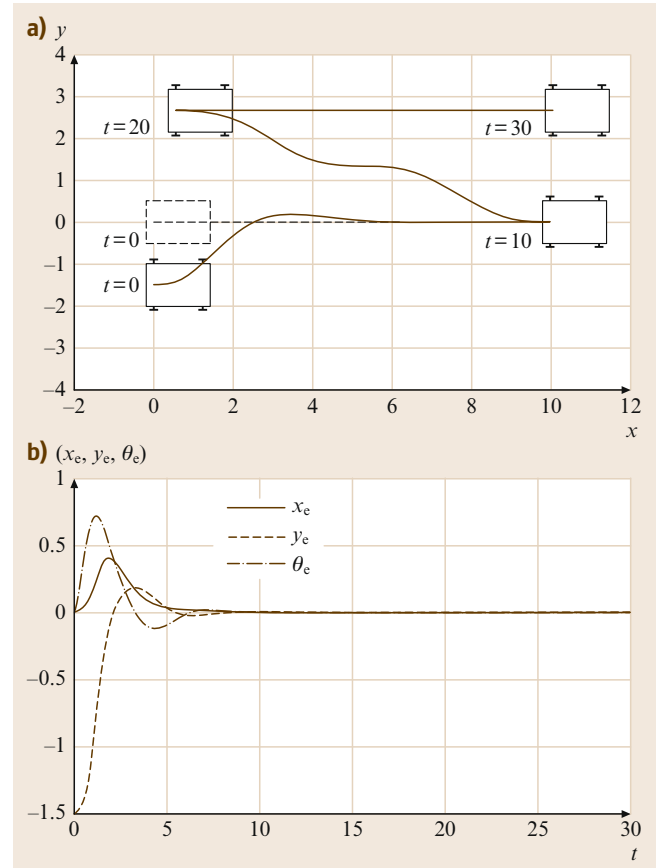

Fig.49.8a,b Tracking of a reference vehicle. **(a)** Cartesian motion; **(b)** error coordinates versus time

with $n \geq 3$. Its proof is a direct extension of the one in the three-dimensional case. The dimension $n = 4$ corresponds to the car case (Sect. 49.4.1). As for a unicycle-type vehicle with N trailers, one has $n = N + 3$. Recall also that, in all cases, z_2 represents the distance d between the path and the point P located at the mid-distance of the rear wheels of the last vehicle. The control objective is then to ensure the convergence of z_2, \dots, z_n to zero. A solution to this problem, which extends the solution (49.27) proposed for the unicycle, is given by

$$v_2 = -v_1 \sum_{i=2}^n \text{sign}(v_1)^{n+1-i} k_i z_i. \quad (49.31)$$

where the control gains k_2, \dots, k_n are chosen such that the polynomial

$$s^{n-1} + k_n s^{n-2} + k_{n-1} s^{n-3} + \dots + k_3 s + k_2$$

is Hurwitz stable. Satisfaction of the constraint $|dc(s)| < 1$ along any solution to the controlled system can also be guaranteed, upon a condition on $(z_2(0), \dots, z_n(0))$ specified in [49.2]. The possibility of adding an integral correction term in (49.31) is also addressed in [49.2].

Simulation Results

The simulation results reported in Fig. 49.9 and VIDEO 181 illustrate how this control scheme performs for a car-like vehicle. The reference curve is the circle of radius equal to four, centered at the origin. The robot's longitudinal velocity u_1 is defined by $u_1 = 1$ for $t \in [0, 5]$, and $u_1 = -1$ for $t > 5$. The control gains have been chosen as $(k_2, k_3, k_4) = (1, 3, 3)$. The motion of the car-like robot in the plane is represented in Fig. 49.9a, and its configuration at times $t = 0, 5$, and 25 are also depicted in the figure. The time evolution of the variables z_2, z_3, z_4 (defined at the end of Sect. 49.4.1) is represented in Fig. 49.9b. One can observe that the (discontinuous) change of the longitudinal velocity u_1 at $t = 5$ does not affect the convergence of these variables to zero.

49.4.4 Asymptotic Stabilization of Fixed Postures

We now consider the problem of asymptotic stabilization of a fixed desired (reference) posture (i. e., position and orientation) for the robot chassis. This problem may be seen as a limit case of the trajectory tracking problem. However, none of the feedback controllers proposed previously in this chapter provides a solution to this problem. From the automatic control point

of view, the asymptotic stabilization of fixed postures is very different from the problems of path following and trajectory tracking with nonzero longitudinal velocity, much in the same way as a human driver knows, from experience, that parking a car at a precise location involves techniques and skills different from those exercised when cruising on a road. In particular, it cannot be solved by any classical control method for linear systems (or based on linearization). Technically, the underlying general problem is the one of asymptotic stabilization of equilibria of controllable driftless systems with less control inputs than state variables. This problem has motivated numerous studies during the last decade of the last century, from many authors and with various angles of attack, and it has remained a subject of active research at the beginning of this century.

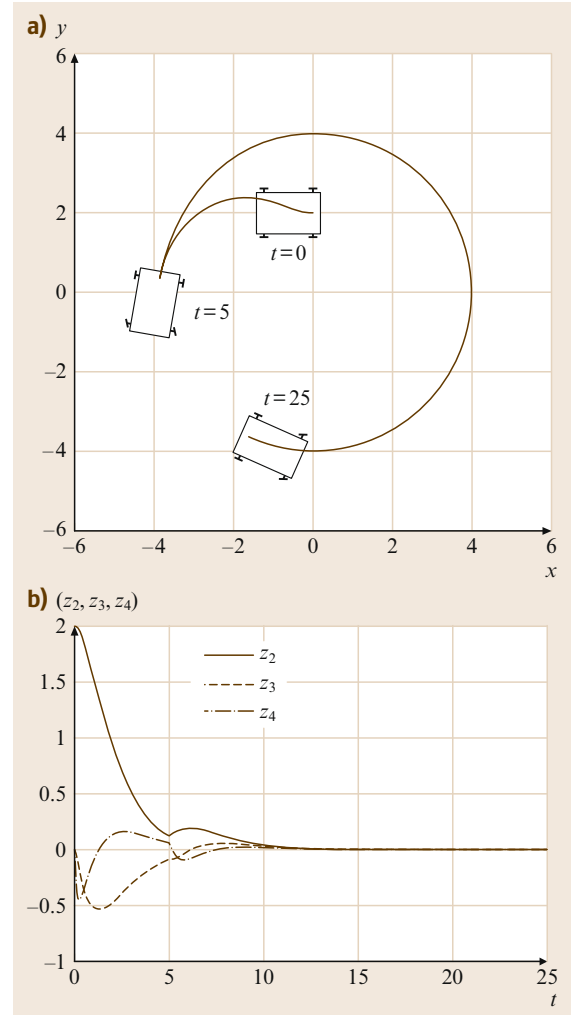

Fig. 49.9a,b Path following along a circle. (a) Cartesian motion; (b) coordinates $z_{2,3,4}$ versus time

The variety of candidate solutions proposed until now, the mathematical technicalities associated with several of them, together with unsolved difficulties and limitations, particularly (but not only) in terms of robustness (an issue on which we will return), prevent us from attempting to cover the subject exhaustively. Instead, we have opted for a somewhat informal exposition of approaches which have been considered, with the illustration of a few control solutions, without going into technical and mathematical details.

A central aspect of the problem, which triggered much of the subsequent research on the control of nonholonomic systems, is that asymptotic stabilization of equilibria (or fixed points) cannot be achieved by using continuous feedbacks which depend on the state only (i. e., continuous pure-state feedbacks). This is a consequence of an important result due to Brockett in 1983. The original result by Brockett concerned differentiable feedbacks; it has later been extended to the larger set of feedbacks which are only continuous.

Theorem 49.1 (Brockett [49.3])

Consider a control system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}) \quad (\mathbf{x} \in \mathbb{R}^n, \mathbf{u} \in \mathbb{R}^m),$$

with \mathbf{f} a differentiable function and $(\mathbf{x}, \mathbf{u}) = (0, 0)$ an equilibrium of this system. A necessary condition for the existence of a continuous feedback control $\mathbf{u}(\mathbf{x})$ which renders the origin of the closed-loop system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}(\mathbf{x}))$$

asymptotically stable is the local surjectivity of the application $(\mathbf{x}, \mathbf{u}) \mapsto \mathbf{f}(\mathbf{x}, \mathbf{u})$. More precisely, the image by \mathbf{f} of any neighborhood Ω of $(0, 0)$ in \mathbb{R}^{n+m} must be a neighborhood of 0 in \mathbb{R}^n .

This result implies that the equilibria of many controllable (nonlinear) systems are not asymptotically stabilizable by continuous pure-state feedbacks. All nonholonomic WMRs belong to this category of systems. This will be shown in the case of a unicycle-type vehicle; the proof for the other mobile robots is similar. Let us thus consider a unicycle-type vehicle, whose kinematic equations (49.4) can be written as $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$ with $\mathbf{x} = (x_1, x_2, x_3)^T$, $\mathbf{u} = (u_1, u_2)^T$, and $\mathbf{f}(\mathbf{x}, \mathbf{u}) = (u_1 \cos x_3, u_1 \sin x_3, u_2)^T$, and let us show that \mathbf{f} is not locally onto in the neighborhood of $(\mathbf{x}, \mathbf{u}) = (0, 0)$. To this purpose, take a vector in \mathbb{R}^3 of the form $(0, \delta, 0)^T$. It is obvious that the equation $\mathbf{f}(\mathbf{x}, \mathbf{u}) = (0, \delta, 0)^T$ does not have a solution in the neighborhood of $(\mathbf{x}, \mathbf{u}) = (0, 0)$ since the first equation, namely $u_1 \cos x_3 = 0$, implies that $u_1 = 0$, so that the second equation cannot have a solution if δ is different from zero.

It is also obvious that the linear approximation about the equilibrium $(\mathbf{x}, \mathbf{u}) = (0, 0)$ of the unicycle kinematic equations is not controllable. If it were, it would be possible to (locally) asymptotically stabilize this equilibrium with a linear (thus continuous) state feedback.

Therefore, by application of the above theorem, a unicycle-type mobile robot (like other nonholonomic robots) cannot be asymptotically stabilized at a desired posture (position/orientation) by using a continuous pure-state feedback. This impossibility has motivated the development of other control strategies in order to solve the problem. Three major types of controls have been considered:

1. *Continuous time-varying feedbacks*, which, besides from depending on the state \mathbf{x} , depend also on the exogenous time variable (i. e., $\mathbf{u}(\mathbf{x}, t)$ instead of $\mathbf{u}(\mathbf{x})$ for classical feedbacks).
2. *Discontinuous feedbacks*, in the classical form $\mathbf{u}(\mathbf{x})$, except that the function \mathbf{u} is not continuous at the equilibrium that one wishes to stabilize.
3. *Hybrid discrete/continuous feedbacks*. Although this class of feedbacks is not defined as precisely as the other two sets of controls, it is mostly composed of time-varying feedbacks, either continuous or discontinuous, such that the part of the control which depends upon the state is only updated periodically, e.g., $\mathbf{u}(t) = \bar{\mathbf{u}}[\mathbf{x}(kT), t]$ for any $t \in [kT, (k+1)T]$, with T denoting a constant period, and $k \in \mathbb{N}$.

We focus hereafter on continuous time-varying feedbacks. Examples of hybrid discrete/continuous feedbacks for unicycle and car-like vehicles are provided in [49.2, Sect 34.4.4], together with associated simulation results. As for discontinuous feedbacks, they involve difficult questions (existence of solutions, mathematical meaning of these solutions, etc.) which complicate their analysis and for which complete answers are not available. Moreover, for most of the discontinuous control strategies described in the literature, the property of stability in the sense of Lyapunov is either not granted or remains an open issue.

The use of time-varying feedbacks for the asymptotic stabilization of a fixed desired equilibrium, for a nonholonomic WMR, in order to circumvent the obstruction pointed out by Brockett's Theorem, was first proposed in [49.4]. Since then, very general results about the stabilization of nonlinear systems by means of time-varying feedbacks have been obtained. For instance, it has been proved that any controllable driftless system can have any of its equilibria asymptotically stabilized with a control of this type [49.5]. This includes the kinematic models of the nonholo-

nomic mobile robots here considered. We will illustrate this approach in the case of unicycle-type and car-like mobile robots modeled by three- and four-dimensional chained systems, respectively. In order to consider the three-dimensional case, let us come back on the results obtained in Sect. 49.4.3 for path following. The control law (49.27), i. e., $v_2 = -v_1 k_2 z_2 - |v_1| k_3 z_3$ applied to the system

$$\begin{cases} \dot{z}_1 = v_1, \\ \dot{z}_2 = v_1 z_3, \\ \dot{z}_3 = v_2, \end{cases}$$

renders the function

$$V(z) := \frac{1}{2}(z_2^2 + \frac{1}{k_2} z_3^2)$$

nonincreasing along any trajectory of the controlled system, i. e.,

$$\dot{V} = -\frac{k_3}{k_2} |v_1| z_3^2,$$

and ensures the convergence of z_2 and z_3 to zero if, for instance, v_1 does not tend to zero as t tends to infinity. For example, if $v_1(t) = \sin t$, z_2 and z_3 tend to zero, and

$$\begin{aligned} z_1(t) &= z_1(0) + \int_0^t v_1(s) ds = z_1(0) + \int_0^t \sin s ds \\ &= z_1(0) + 1 - \cos t, \end{aligned}$$

so that $z_1(t)$ oscillates around the mean value $z_1(0) + 1$. To reduce these oscillations, one can multiply v_1 by a factor which depends on the current state. Take, for example, $v_1(z, t) = \|(z_2, z_3)\| \sin t$, that we complement with a stabilizing term like $-k_1 z_1$ with $k_1 > 0$, i. e.,

$$v_1(z, t) = -k_1 z_1 + \|(z_2, z_3)\| \sin t.$$

The feedback control so obtained is time-varying and asymptotically stabilizing.

Proposition 49.2

The continuous time-varying feedback

$$\begin{cases} v_1(z, t) = -k_1 z_1 + \alpha \|(z_2, z_3)\| \sin t, \\ v_2(z, t) = -v_1(z, t) k_2 z_2 - |v_1(z, t)| k_3 z_3, \end{cases} \quad (49.32)$$

with $\alpha, k_{1,2,3} > 0$, renders the origin of the 3-D chained system globally asymptotically stable [49.6].

The above proposition can be extended to chained systems of arbitrary dimension [49.6]. For the case $n = 4$, which corresponds to the car-like robot, one has the following result.

Proposition 49.3

The continuous time-varying feedback

$$\begin{cases} v_1(z, t) = -k_1 z_1 + \alpha \|(z_2, z_3, z_4)\| \sin t, \\ v_2(z, t) = -|v_1(z, t)| k_2 z_2 - v_1(z, t) k_3 z_3 \\ \quad - |v_1(z, t)| k_4 z_4, \end{cases} \quad (49.33)$$

with $\alpha, k_{1,2,3,4} > 0$ chosen such that the polynomial $s^3 + k_4 s^2 + k_3 s + k_2$ is Hurwitz stable, renders the origin of the 4-D chained system globally asymptotically stable [49.6].

Figure 49.10 below illustrates the previous result. For this simulation, the parameters $\alpha, k_{1,2,3,4}$ in the feedback law (49.33) have been chosen as $\alpha = 3$ and $k_{1,2,3,4} = (1.2, 10, 18, 17)$. Figure 49.10a shows the motion of the car-like robot in the plane. The initial configuration, at time $t = 0$, is depicted in plain lines, whereas the desired configuration is shown in dashed lines. The time evolution of the variables x , y , and θ (i. e., the position and orientation variables corresponding to the model (49.5)) is shown in Fig. 49.10b.

A shortcoming of this type of control, very clear from this simulation, is that the system's state converges to zero quite slowly. One can show that the rate of convergence is only polynomial, i. e., it is commensurable with $t^{-\alpha}$ (for some $\alpha \in (0, 1)$) for most of the trajectories of the controlled system. This slow rate of convergence is related to the fact that the control function is Lipschitz-continuous with respect to x . It is a characteristics of systems the linear approximation of which is not stabilizable. Indeed, it can be shown that exponential stability (in the classical sense of linear systems) of an equilibrium point of a nonlinear system cannot be obtained with a Lipschitz-continuous feedback when the system's linear approximation at that point is not stabilizable ([49.2, Prop. 34.11] for a precise statement and details). The need of better performance and efficiency, has triggered the development of stabilizing time-varying feedbacks which are continuous, but not Lipschitz-continuous. Examples of such feedbacks, yielding uniform exponential convergence, are given in the following propositions for chained systems of dimension three and four, respectively.

Proposition 49.4

Let $\alpha, k_{1,2,3} > 0$ denote scalars such that the polynomial $p(s) = s^2 + k_3 s + k_2$ is Hurwitz stable. For any integers $p, q \in \mathbb{N}^*$, let $\rho_{p,q}$ denote the function defined on \mathbb{R}^2 by

$$\begin{aligned} \forall \bar{z}_2 = (z_2, z_3) \in \mathbb{R}^2, \rho_{p,q}(\bar{z}_2) \\ = \left(|z_2|^{\frac{p}{q+1}} + |z_3|^{\frac{p}{q}} \right)^{\frac{1}{p}}. \end{aligned}$$

Then, there exists $q_0 > 1$ such that, for any $q \geq q_0$ and $p > q + 2$, the continuous state feedback

$$\begin{cases} v_1(z, t) = -k_1(z_1 \sin t - |z_1|) \sin t \\ \quad + \alpha \rho_{p,q}(\bar{z}_2) \sin t \\ v_2(z, t) = -v_1(z, t) k_2 \frac{z_2}{\rho_{p,q}^2(\bar{z}_2)} - |v_1(z, t)| k_3 \frac{z_3}{\rho_{p,q}(\bar{z}_2)} \end{cases} \quad (49.34)$$

renders the origin of the three-dimensional chained system globally asymptotically stable, with a uniform exponential rate of convergence [49.7].

The parenthood of the controls (49.32) and (49.34) is noticeable. One can also verify that the control (49.34) is well defined (by continuity) at $\bar{z}_2 = 0$. More precisely,

the ratios

$$\frac{z_2}{\rho_{p,q}^2(\bar{z}_2)} \quad \text{and} \quad \frac{z_3}{\rho_{p,q}(\bar{z}_2)},$$

which are obviously well defined when $\bar{z}_2 \neq 0$, tend to zero when \bar{z}_2 tends to zero. This guarantees the continuity of the control law.

The property of exponential convergence pointed out in the above result calls for some remarks. Indeed, this property does not exactly correspond to the classical exponential convergence property associated with stable linear systems. In this latter case, exponential convergence means that for some constant K , γ , and along any solution to the controlled system, one has

$$\|z(t)\| \leq K \|z(t_0)\| e^{-\gamma(t-t_0)}$$

This corresponds to the common notion of *exponential stability*. In the present case, this inequality becomes

$$\rho[z(t)] \leq K \rho[z(t_0)] e^{-\gamma(t-t_0)}$$

for some function ρ , defined for example by

$$\rho(z) = |z_1| + \rho_{p,q}(z_2, z_3),$$

with $\rho_{p,q}$ as specified in Proposition 49.4. Although the function ρ shares common features with the Euclidean norm of the state vector (it is definite positive and it tends to infinity when $\|z\|$ tends to infinity), it is not equivalent to this norm. Of course, this does not change the fact that each component z_i of z converges to zero exponentially. However, the transient behavior is different because one only has

$$|z_i(t)| \leq K \|z(t_0)\|^\alpha e^{-\gamma(t-t_0)},$$

with $\alpha < 1$, instead of

$$|z_i(t)| \leq K \|z(t_0)\| e^{-\gamma(t-t_0)}.$$

In the case of the four-dimensional chained system, one can establish the following result, which is similar to Proposition 49.4.

Proposition 49.5

Let $\alpha, k_1, k_2, k_3, k_4 > 0$ be chosen such that the polynomial $p(s) = s^3 + k_4 s^2 + k_3 s + k_2$ is Hurwitz stable. For any integers $p, q \in \mathbb{N}^*$, let $\rho_{p,q}$ denote the function defined on \mathbb{R}^3 by

$$\rho_{p,q}(\bar{z}_2) = \left(|z_2|^{\frac{p}{q+2}} + |z_3|^{\frac{p}{q+1}} + |z_4|^{\frac{p}{q}} \right)^{\frac{1}{p}}$$

with $\bar{z}_2 = (z_2, z_3, z_4) \in \mathbb{R}^3$. Then, there exists $q_0 > 1$ such that, for any $q \geq q_0$ and $p > q + 2$, the continuous

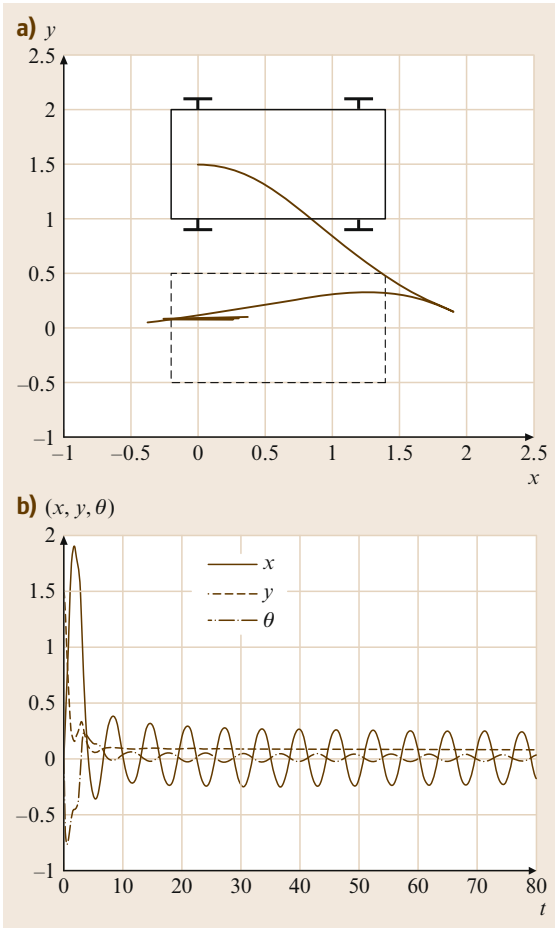

Fig.49.10a,b Asymptotic stabilization with a Lipschitz-continuous controller. (a) Cartesian motion; (b) error coordinates versus time

state feedback

$$\begin{cases} v_1(z, t) = -k_1(z_1 \sin t - |z_1|) \sin t \\ \quad + \alpha \rho_{p,q}(\bar{z}_2) \sin t, \\ v_2(z, t) = -|v_1(z, t)| k_2 \frac{z_2}{\rho_{p,q}^3(\bar{z}_2)} - v_1(z, t) k_3 \frac{z_3}{\rho_{p,q}^2(\bar{z}_2)} \\ \quad - |v_1(z, t)| k_4 \frac{z_4}{\rho_{p,q}(\bar{z}_2)}, \end{cases} \quad (49.35)$$

renders the origin of the 4-D chained system globally asymptotically stable, with a uniform exponential rate of convergence [49.7].

The performance of the control law (49.35) is illustrated by the simulation results shown in Fig. 49.11. The control parameters have been chosen as follows: $\alpha = 0.6$, $k_{1,2,3,4} = (1.6, 10, 18, 17)$, $q = 2$, $p = 5$. The comparison with the simulation results of Fig. 49.10 shows a clear gain in performance.

49.4.5 Limitations Inherent to the Control of Nonholonomic Systems

Let us first mention some problems associated with the nonlinear time-varying feedbacks just presented. An ever important issue, when studying feedback control, is robustness. Indeed, if it were not for the sake of robustness, feedback control would lose much of its value and interest with respect to open-loop control solutions. There are various robustness issues. One of them concerns the sensitivity to modeling errors. For instance, in the case of a unicycle-type robot whose kinematic equations are in the form $\dot{x} = u_1 b_1(x) + u_2 b_2(x)$, one would like to know whether a feedback law which stabilizes an equilibrium of this system also stabilizes this equilibrium for the *neighbor* system $\dot{x} = u_1[b_1(x) + \varepsilon g_1(x)] + u_2[b_2(x) + \varepsilon g_2(x)]$, with g_1 and g_2 denoting continuous applications, and ε a parameter which quantifies the modeling error. This type of error can account, for example, for a small uncertainty concerning the orientation of the actuated wheels axle with respect to the chassis, which results in a bias in the measurement of this orientation. One can show that time-varying control laws like (49.34) are not robust with respect to this type of error in the sense that, for certain functions g_1 and g_2 , and for ε arbitrarily small, the system's solutions end up oscillating in the neighborhood of the origin, instead of converging to the origin. In other words, both the properties of stability of the origin and of convergence to this point can be jeopardized by arbitrarily small modeling errors, even in the absence of measurement noise. In view of these problems, one is brought to question

the existence of fast (exponential) stabilizers endowed with robustness properties similar to those of stabilizing linear feedbacks for linear systems. The answer is that, to our knowledge, no such control solution (either continuous or discontinuous) has ever been found. More than likely such a solution does not exist for nonholonomic systems. Robustness of the stability property against modeling errors, and control discretization and delays, has been proved in some cases, but this could only be achieved with Lipschitz-continuous feedbacks which, as we have seen, yield slow convergence. The classical compromise between robustness and performance thus seems much more acute than in the case of stabilizable linear systems (or nonlinear systems whose linear approximation is stabilizable).

A second issue is the proven nonexistence of a *universal* feedback controller capable of stabilizing any feasible reference state trajectory asymptotically [49.8].

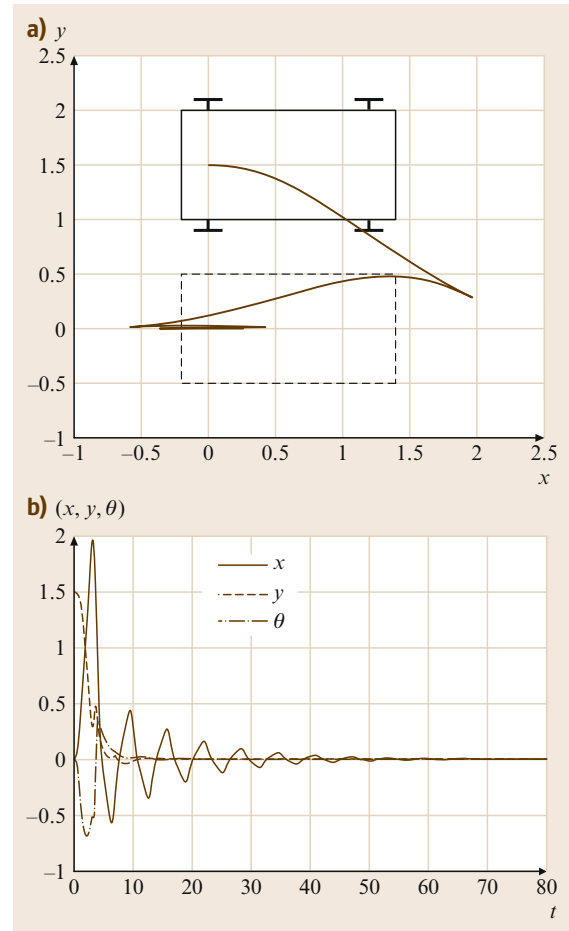

Fig. 49.11a,b Asymptotic stabilization with a continuous (non-Lipschitz) time-varying feedback. **(a)** Cartesian motion; **(b)** error coordinates versus time

This is another notable difference with the linear case. Indeed, given a controllable linear system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$, the feedback controller $\mathbf{u} = \mathbf{u}_r + \mathbf{K}(\mathbf{x} - \mathbf{x}_r)$, with \mathbf{K} a gain matrix such that $\mathbf{A} + \mathbf{B}\mathbf{K}$ is Hurwitz stable, exponentially stabilizes any feasible reference trajectory \mathbf{x}_r (solution to the system) associated with the control input \mathbf{u}_r . The nonexistence of such a controller, in the case of nonholonomic mobile robots, is related to the conditions upon the longitudinal velocity stated in previous propositions concerning trajectory stabilization. This basically indicates that such conditions cannot be removed entirely: whatever the chosen feedback controller, there always exists a feasible reference trajectory that this feedback cannot asymptotically stabilize. Note that this limitation persists when considering non-standard feedbacks (such as, e.g., time-varying periodic feedbacks capable of asymptotically stabilizing reference trajectories which are reduced to a single point). Moreover, it has clear practical consequences because there are applications (automatic tracking of a human-driven car, for instance) for which the reference trajectory, and thus its properties, are not known in advance (is the leading car going to keep moving or stop?) so that one cannot easily decide on which controller to use. Switching between various controllers is a possible strategy, which has been studied by some authors and may give satisfactory results in many situations. However, since implementing a predefined switching strategy between two controllers sums up to designing a third controller, this does not solve the core of the problem nor grant any certitude of success.

A third issue, which is not specific to nonholonomic systems, but has seldom been addressed in the nonlinear control literature, concerns the problem of tracking *nonfeasible* trajectories (i.e., trajectories which are not solutions to the system's equations). Since exact tracking is not possible, by the definition of a nonfeasible trajectory, the control objective is then to ensure that the tracking errors shrink to, and ever after never exceed, certain nonzero thresholds. The fact that these thresholds can theoretically be arbitrarily small in the case of nonholonomic systems, if the amplitude of the velocity control inputs is not limited, makes this problem particularly relevant for these systems. This can be termed as a *practical* stabilization objective which, although slightly less ambitious than the objective of asymptotic stabilization considered in previous sections, opens up both the control design problem and the range of applications significantly. For instance, it allows one to address the problem of tracking an omnidirectional vehicle with a unicycle-type, or a car-like, vehicle. In the context of planning a trajectory with obstacle avoidance, transforming a nonfeasible trajectory into a feasible approximation for a certain mobile robot

can be performed by applying a practical stabilizer to a model of this robot and by numerical integration of the system's closed-loop equations. Also, if one reformulates the former question about the existence of a *universal* stabilizer, with the objective of asymptotic stabilization now replaced by the one of practical stabilization, then the answer becomes positive: such a stabilizer exists and, moreover, the reference trajectories do not even have to be feasible.

49.4.6 Practical Stabilization of Arbitrary Trajectories

A possible approach for the design of practical stabilizers in the case of controllable driftless systems is described in [49.9]. Some of its basic principles, here adapted to the specific examples of unicycle-type and car-like mobile robots, are recalled next.

Let us introduce some matrix notation that will be used in this section.

$$\mathbf{R}(\theta) = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}, \quad \mathbf{S} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

$$\bar{\mathbf{R}}(\theta) = \begin{pmatrix} \mathbf{R}(\theta) & 0 \\ 0 & 1 \end{pmatrix}.$$

Unicycle Case

With the above notation, the kinematic model (49.4) can be written as

$$\dot{\mathbf{g}} = \bar{\mathbf{R}}(\theta)\mathbf{C}\mathbf{u}, \quad (49.36)$$

with $\mathbf{g} = (\mathbf{x}, y, \theta)'$ and

$$\mathbf{C} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

Let us now consider a smooth function

$$f: \alpha \mapsto f(\alpha) = \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \\ f_\theta(\alpha) \end{pmatrix},$$

with $\alpha \in S^1 = \mathbb{R}/2\pi\mathbb{Z}$ (i.e., α is an angle variable), and define

$$\bar{\mathbf{g}} := \begin{pmatrix} \bar{x} \\ \bar{y} \\ \bar{\theta} \end{pmatrix} := \mathbf{g} - \bar{\mathbf{R}}(\theta - f_\theta(\alpha))f(\alpha)$$

$$= \begin{pmatrix} x \\ y \\ \theta - f_\theta(\alpha) \end{pmatrix} - \mathbf{R}(\theta - f_\theta(\alpha)) \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \end{pmatrix}. \quad (49.37)$$

Note that \bar{g} can be viewed as the situation of a frame $\bar{\mathcal{F}}_m(\alpha)$ the origin of which has components

$$-\mathbf{R}(-f_\theta(\alpha)) \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \end{pmatrix}$$

in the frame \mathcal{F}_m . In term of differential geometry, \bar{g} is the product of g by the inverse $f(\alpha)^{-1}$ of $f(\alpha)$, in the sense of the Lie group operations in $SE(2)$. Hence, $\bar{\mathcal{F}}_m(\alpha)$ is all the closer to \mathcal{F}_m as the components of $f(\alpha)$ are small. For any smooth time function $t \mapsto \alpha(t)$, and along any solution to system (49.36), the time derivative of \bar{g} is given by

$$\dot{\bar{g}} = \bar{\mathbf{R}}(\bar{\theta})\bar{u}, \quad (49.38)$$

with

$$\bar{u} = \mathbf{A}(\alpha) \left(\bar{\mathbf{R}}(f_\theta(\alpha)) - \frac{\partial f}{\partial \alpha}(\alpha) \right) \begin{pmatrix} \mathbf{C}u \\ \dot{\alpha} \end{pmatrix}, \quad (49.39)$$

and

$$\mathbf{A}(\alpha) = \begin{pmatrix} I_2 & -S \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \end{pmatrix} \\ 0 & 1 \end{pmatrix}. \quad (49.40)$$

From (49.38) and (49.39), one can view $\dot{\alpha}$ as a complementary control input that can be used to monitor the motion of the frame $\bar{\mathcal{F}}_m(\alpha)$. More precisely, $\bar{\mathcal{F}}_m(\alpha)$ can be viewed as an omnidirectional frame provided that \bar{u} can be rendered equal to any vector of \mathbb{R}^3 , i. e., provided that the mapping $(u, \dot{\alpha}) \mapsto \bar{u}$ is onto. Let us determine when this condition is satisfied. Equation (49.39) can also be written as

$$\bar{u} = \mathbf{A}(\alpha)\mathbf{H}(\alpha) \begin{pmatrix} u \\ \dot{\alpha} \end{pmatrix}, \quad (49.41)$$

with

$$\mathbf{H}(\alpha) = \begin{pmatrix} \cos f_\theta(\alpha) & 0 & -\frac{\partial f_x}{\partial \alpha}(\alpha) \\ \sin f_\theta(\alpha) & 0 & -\frac{\partial f_y}{\partial \alpha}(\alpha) \\ 0 & 1 & -\frac{\partial f_\theta}{\partial \alpha}(\alpha) \end{pmatrix}. \quad (49.42)$$

Since $\mathbf{A}(\alpha)$ is invertible, $\bar{\mathcal{F}}_m(\alpha)$ is omnidirectional if and only if the matrix $\mathbf{H}(\alpha)$ is also invertible. A function f which satisfies this property for any $\alpha \in S^1$ is called a *transverse function* [49.10]. The issue of the existence of such functions has been treated in the much more general context of the transverse function

approach [49.9, 10]. In the present case, a family of transverse functions is given by

$$f(\alpha) = \begin{pmatrix} \varepsilon \sin \alpha \\ \varepsilon^2 \eta \frac{\sin 2\alpha}{4} \\ \arctan(\varepsilon \eta \cos \alpha) \end{pmatrix} \quad \text{with } \varepsilon, \eta > 0. \quad (49.43)$$

Indeed, with this function one can verify that, for any $\alpha \in S^1$,

$$\det \mathbf{H}(\alpha) = -\frac{\varepsilon^2 \eta}{2} \cos(\arctan(\varepsilon \eta \cos \alpha)) < 0.$$

Note that the components of f uniformly tend to zero as ε tends to zero, so that the associated omnidirectional frame $\bar{\mathcal{F}}_m(\alpha)$ can be made arbitrarily close to \mathcal{F}_m by choosing ε small (but different from zero).

Now, let

$$t \mapsto \mathbf{g}_r(t) = [\mathbf{x}_r(t), \mathbf{y}_r(t), \theta_r(t)]^T$$

denote a smooth, but otherwise *arbitrary*, reference trajectory. It is not difficult to derive from (49.38) a feedback law \bar{u} which asymptotically stabilizes \bar{g} at \mathbf{g}_r . A possible choice is given by

$$\bar{u} = \bar{\mathbf{R}}(-\bar{\theta})[\dot{\mathbf{g}}_r - k(\bar{\mathbf{g}} - \mathbf{g}_r)], \quad (49.44)$$

which implies that

$$(\dot{\bar{\mathbf{g}}} - \dot{\mathbf{g}}_r) = -k(\bar{\mathbf{g}} - \mathbf{g}_r)$$

and therefore that $\bar{\mathbf{g}} - \mathbf{g}_r = 0$ is an exponentially stable equilibrium of the above equation for any $k > 0$. Then, it follows from (49.37) that

$$\lim_{t \rightarrow +\infty} \{g(t) - \mathbf{g}_r(t) - \bar{\mathbf{R}}[\theta_r(t)]f[\alpha(t)]\} = 0. \quad (49.45)$$

The norm of the tracking error $\|\mathbf{g} - \mathbf{g}_r\|$ is thus ultimately bounded by the norm of $f(\alpha)$ which, in view of (49.43), can be made arbitrarily small via the choice of ε . It is in this sense that practical stabilization is achieved. The control u for the unicycle-like robot is then calculated by inverting the relation (49.41) and using the expression (49.44) of \bar{u} .

While it can be tempting to use very small values of ε for the transverse function f in order to obtain a good tracking precision, one must be aware of the limits of this strategy. Indeed, when ε tends to

zero, the matrix $\mathbf{H}(\alpha)$ defined by (49.42) becomes ill-conditioned, and its determinant tends to zero. This implies, by (49.41), that the robot's velocities u_1 and u_2 may become very large. In particular, when the reference trajectory \mathbf{g}_r is not feasible, many manoeuvres are likely to occur. Note that this difficulty is intrinsic to the robot's nonholonomy and that it cannot be circumvented (think about the problem of parking a car in a very narrow parking place). For this reason, trying to impose very accurate tracking of nonfeasible trajectories is not necessarily a good option in practice. On the other hand, when the trajectory is feasible, manoeuvres are not needed to achieve accurate tracking, so that smaller values of ε can be used in this case. This clearly leads to a dilemma when the reference trajectory is not known in advance and its properties in term of feasibility can vary with time. A control strategy which addresses this issue, based on the use of transverse functions whose magnitude can be adapted online, is proposed in [49.11]. Experimental validations of the present approach on a unicycle-like robot can also be found in [49.12].

Car Case

The control approach presented above can be extended to car-like vehicles (and also to the trailer case). Again, the idea is to associate with the robot's frame \mathcal{F}_m an omnidirectional *companion* frame $\tilde{\mathcal{F}}_m(\alpha)$ which can be maintained arbitrarily close to \mathcal{F}_m via the choice of some design parameters. Let us show how this can be done for a car-like vehicle. To simplify the forthcoming equations, let us rewrite system (49.5) as

$$\begin{cases} \dot{x} = u_1 \cos \theta, \\ \dot{y} = u_1 \sin \theta, \\ \dot{\theta} = u_1 \xi, \\ \dot{\xi} = u_\xi, \end{cases}$$

with $\xi = (\tan \phi)/L$ and $u_\xi = u_2(1 + \tan^2 \phi)/L$. This system can also be written as (compare with (49.36))

$$\begin{cases} \dot{\mathbf{g}} = \bar{\mathbf{R}}(\theta) \mathbf{C}(\xi) u_1, \\ \dot{\xi} = u_\xi, \end{cases} \quad (49.46)$$

with $\mathbf{g} = (x, y, \theta)^T$ and $\mathbf{C}(\xi) = (1, 0, \xi)^T$. Let us now consider a smooth function

$$f : \alpha \mapsto f(\alpha) = \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \\ f_\theta(\alpha) \\ f_\xi(\alpha) \end{pmatrix},$$

with $\alpha \in S^1 \times S^1$ (i. e., $\alpha = (\alpha_1, \alpha_2)$), and define (compare with (49.37))

$$\begin{aligned} \bar{\mathbf{g}} &:= \begin{pmatrix} \bar{x} \\ \bar{y} \\ \bar{\theta} \end{pmatrix} := \mathbf{g} - \bar{\mathbf{R}}(\theta - f_\theta(\alpha)) f_g(\alpha) \\ &= \begin{pmatrix} x \\ y \\ \theta - f_\theta(\alpha) \end{pmatrix} - \mathbf{R}(\theta - f_\theta(\alpha)) \begin{pmatrix} f_x(\alpha) \\ f_y(\alpha) \end{pmatrix}, \end{aligned} \quad (49.47)$$

which, as in the unicycle case, can be viewed as the situation of some *companion* frame $\tilde{\mathcal{F}}_m(\alpha)$. By differentiating $\bar{\mathbf{g}}$ along any smooth time function $t \mapsto \alpha(t)$ and any solution to system (49.46), one can verify that (49.38) is still satisfied, except that $\bar{\mathbf{u}}$ is now given by

$$\begin{aligned} \bar{\mathbf{u}} &= \mathbf{A}(\alpha) \left(\bar{\mathbf{R}}[f_\theta(\alpha)] - \frac{\partial f_g}{\partial \alpha_1}(\alpha) - \frac{\partial f_g}{\partial \alpha_2}(\alpha) \right) \\ &\quad \times \begin{pmatrix} \mathbf{C}(\xi) u_1 \\ \dot{\alpha}_1 \\ \dot{\alpha}_2 \end{pmatrix} \end{aligned} \quad (49.48)$$

rather than by (49.39) (with $\mathbf{A}(\alpha)$ still defined by (49.40)). Using the fact that

$$\begin{aligned} \mathbf{C}(\xi) u_1 &= \mathbf{C}(f_\xi(\alpha)) u_1 + \{\mathbf{C}(\xi) - \mathbf{C}(f_\xi(\alpha))\} u_1 \\ &= \begin{pmatrix} 1 \\ 0 \\ f_\xi(\alpha) \end{pmatrix} u_1 + \begin{pmatrix} 0 \\ 0 \\ \xi - f_\xi(\alpha) \end{pmatrix} u_1, \end{aligned}$$

(49.48) can also be written as

$$\bar{\mathbf{u}} = A(\alpha) \mathbf{H}(\alpha) \begin{pmatrix} u_1 \\ \dot{\alpha}_1 \\ \dot{\alpha}_2 \end{pmatrix} + A(\alpha) \begin{pmatrix} 0 \\ 0 \\ u_1 [\xi - f_\xi(\alpha)] \end{pmatrix}, \quad (49.49)$$

with

$$\mathbf{H}(\alpha) = \begin{pmatrix} \cos f_\theta(\alpha) & -\frac{\partial f_x}{\partial \alpha_1}(\alpha) & -\frac{\partial f_x}{\partial \alpha_2}(\alpha) \\ \sin f_\theta(\alpha) & -\frac{\partial f_y}{\partial \alpha_1}(\alpha) & -\frac{\partial f_y}{\partial \alpha_2}(\alpha) \\ f_\xi(\alpha) & -\frac{\partial f_\theta}{\partial \alpha_1}(\alpha) & -\frac{\partial f_\theta}{\partial \alpha_2}(\alpha) \end{pmatrix}. \quad (49.50)$$

By setting

$$\mathbf{u}_\xi = \dot{f}_\xi(\alpha) - k(\xi - f_\xi(\alpha)), \quad (49.51)$$

with $k > 0$, it follows from (49.46) that $\xi - f_\xi(\alpha)$ exponentially converges to zero. Hence, after some transient phase whose duration is commensurable with $1/k$, $\xi - f_\xi(\alpha) \approx 0$, and (49.49) reduces to

$$\bar{\mathbf{u}} = \mathbf{A}(\alpha)\mathbf{H}(\alpha) \begin{pmatrix} u_1 \\ \dot{\alpha}_1 \\ \dot{\alpha}_2 \end{pmatrix}. \quad (49.52)$$

Provided that the function f is such that $\mathbf{H}(\alpha)$ is always invertible, this latter relation means that the frame $\bar{\mathcal{F}}_m(\alpha)$ associated with $\bar{\mathbf{g}}$ is omnidirectional. Any function f for which this property is satisfied is called a transverse function. Once it has been determined, one can proceed as in the unicycle case to asymptotically stabilize an arbitrary reference trajectory \mathbf{g}_r for $\bar{\mathbf{g}}$, for example, by defining $\bar{\mathbf{u}}$ as in (49.44). The control u_1 for the car is then obtained by inverting relation (49.52).

The following lemma specifies a family of transverse functions for the car case.

Lemma 49.1

For any $\varepsilon > 0$ and any η_1, η_2, η_3 such that $\eta_1, \eta_2, \eta_3 > 0$ and $6\eta_2\eta_3 > 8\eta_3 + \eta_1\eta_2$, the function f defined by

$$f(\alpha) = \begin{pmatrix} \bar{f}_1(\alpha) \\ \bar{f}_4(\alpha) \\ \arctan(\bar{f}_3(\alpha)) \\ \bar{f}_2(\alpha)\cos^3\bar{f}_3(\alpha) \end{pmatrix}$$

with

$$\bar{f} : S^1 \times S^1 \longrightarrow \mathbb{R}^4$$

given by

$$\bar{f}(\alpha) = \begin{pmatrix} \varepsilon(\sin \alpha_1 + \eta_2 \sin \alpha_2) \\ \varepsilon \eta_1 \cos \alpha_1 \\ \varepsilon^2 \left(\frac{\eta_1 \sin 2\alpha_1}{4} - \eta_3 \cos \alpha_2 \right) \\ \varepsilon^3 \left(\eta_1 \frac{\sin^2 \alpha_1 \cos \alpha_1}{6} - \frac{\eta_2 \eta_3 \sin 2\alpha_2}{4} - \eta_3 \sin \alpha_1 \cos \alpha_2 \right) \end{pmatrix},$$

satisfies the transversality condition $\det \mathbf{H}(\alpha) \neq 0 \forall \alpha$, with $\mathbf{H}(\alpha)$ defined by (49.50) [49.13].

The simulation results reported in Fig. 49.12 illustrate the application of this control approach for a car-like robot. The reference trajectory is defined by the initial condition $\mathbf{g}_r(0) = 0$ and its time derivative

$$\dot{\mathbf{g}}_r(t) = \begin{cases} (0, 0, 0)^T & \text{if } t \in [0, 30] \\ (1, 0, 0)^T & \text{if } t \in [30, 38] \\ (0, 0.3, 0)^T & \text{if } t \in [38, 53] \\ (-1, 0, 0)^T & \text{if } t \in [53, 61] \\ (0, 0, 0.2)^T & \text{if } t \in [61, 80] \end{cases}.$$

This corresponds to a fixed situation when $t \in [0, 30]$, three sequences of pure translational motion when $t \in [30, 61]$, and a pure rotational motion when $t \in [61, 80]$. Let us remark that this trajectory is not feasible for the car-like robot when $t \in [38, 53]$, since it corresponds to a lateral translation in the direction of the unit vector \mathbf{j}_r of the frame \mathcal{F}_r associated with \mathbf{g}_r , nor when $t \in [61, 80]$, since a rear-drive car cannot perform pure rotational motion. The initial configuration of the car-like robot, at $t = 0$, is $\mathbf{g}(0) = (0, 1.5, 0)$, and the initial steering wheel angle is $\phi(0) = 0$.

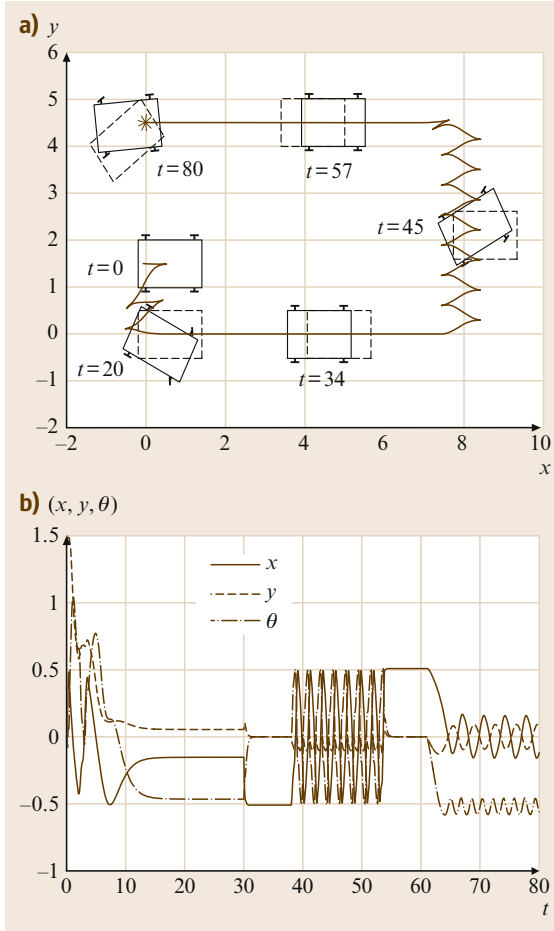

Fig.49.12a,b Practical stabilization of an arbitrary trajectory by the transverse function approach. (a) Cartesian motion; (b) error coordinates versus time

In Fig. 49.12a, the robot is drawn with a solid line at several time instants, whereas the chassis of the reference vehicle is shown as a dashed line at the same time instants. The figure also shows the trajectory of the point located at the mid-distance of the robot's rear wheels. Figure 49.12b shows the time evolution of the tracking error expressed in the reference frame (i. e., (x_e, y_e) as defined by (49.16), and $\theta_e = \theta - \theta_r$). It follows from (49.45) that, after the transient phase associated with the exponential convergence of \bar{g} to zero, the ultimate bound for $|x_e|$, $|y_e|$, and $|\theta_e|$ is upper-bounded by the maximum amplitude of the functions f_x , f_y , and f_θ , respectively. For this simulation, the control param-

eters of the transverse function f of Lemma 49.1 have been chosen as follows: $\varepsilon = 0.17$, $\eta_{1,2,3} = (12, 2, 20)$. With these values, one can verify that $|f_x|$, $|f_y|$, and $|f_\theta|$ are bounded by 0.51, 0.11, and 0.6, respectively. This is consistent with the time evolution of the tracking error observed in the figure. As pointed out for the unicycle case, tracking errors could be diminished by decreasing the value of ε , but this would involve larger values of the control inputs and also more frequent manoeuvres, especially on the time intervals [38, 53] and [61, 80] when the reference trajectory is not feasible. Additional simulation and experimental results on this approach are illustrated by [VIDEO 182](#) and [VIDEO 243](#).

49.5 Path Following in the Case of Nonideal Wheel–Ground Contact

The kinematic models used in the previous sections are derived under the classical rolling-without-sliding assumption for the vehicle's wheels. This assumption is satisfied with a good degree of accuracy for many applications both indoor and outdoor (e.g., on-road). In some cases, however, sliding can be significant. This happens for example when a vehicle operates on natural terrain with poor grip conditions (grass, earth) and when the vehicle's speed is significant and/or the terrain is not perfectly horizontal. In these cases, the control laws presented in the previous sections may not give full satisfaction. We show in this section that these control laws can still be used successfully, provided that sliding is taken into account at the modelling level and estimated online via a dedicated observer. For simplicity, only the path following problem is addressed, but the techniques here presented can be extended to other control problems.

Fig. 49.13 Car-like vehicle in the presence of sliding

49.5.1 Extended Control Models in the Presence of Sliding

Extended Kinematic Model

Consider the two-wheels schematic representation of a car-like vehicle on Fig. 49.13. The angles β_R and β_F are introduced in order to represent the sliding of the rear and front wheels respectively. More precisely, denoting the centres of the rear and front wheels as P_R and P_F respectively, β_R is the angle between the vector $\overrightarrow{P_R P_F}$ and the velocity vector \mathbf{v}_R of P_R , whereas β_F represents the angle between the steering direction and the velocity vector \mathbf{v}_F of P_F . The kinematic modeling of Sect. 49.2 is easily extended to the present case [49.14], resulting in the following model

$$\begin{cases} \dot{x} = u_1 \cos(\theta + \beta_R) \\ \dot{y} = u_1 \sin(\theta + \beta_R) \\ \dot{\theta} = u_1 \cos(\beta_R) \frac{\tan(\phi + \beta_F) - \tan(\beta_R)}{L} \\ \dot{\phi} = u_2 \end{cases} \quad (49.53)$$

with u_1 the (signed) intensity of the vector \mathbf{v}_R . Note that these equations reduce to (49.5) when $\beta_F = \beta_R = 0$.

Kinematic Model in a Frénet Frame

In the context of path following, a kinematic model with reference to a Frénet frame moving along the desired path is obtained via a straightforward adaptation of the pure-rolling case discussed in Sect. 49.2.3. Defining the distance between the vehicle and the desired path C as the distance d between the point P_R and this path (Fig. 49.5), the equations of this model are readily de-

duced from (49.53) (compare with (49.13))

$$\begin{cases} \dot{s} = u_1 \frac{\cos(\theta_e + \beta_R)}{1 - d c(s)} \\ \dot{d} = u_1 \sin(\theta_e + \beta_R) \\ \dot{\theta}_e = u_1 [\cos(\beta_R) \lambda_1 - \lambda_2] \\ \dot{\phi} = u_2 \end{cases}, \quad (49.54)$$

with θ_e the angle between the vehicle's body axis $P_R P_F$ and the tangent to the desired path evaluated at the projection of the point P_R on this path, $c(s)$ the path curvature at the projected point, $\lambda_1 = (\tan(\phi + \beta_F) - \tan(\beta_R))/L$ and $\lambda_2 = (c(s) \cos(\theta_e + \beta_R))/(1 - d c(s))$.

Dynamic Model of Sliding Angles

The kinematic model (49.53) can be used for control design once it is completed by a model of the dynamics of the sliding angles β_R and β_F . Such a model can be obtained from Newton's law and a model of tire/ground interactions. A few notation (Fig. 49.14 for details) and assumptions are introduced for this purpose:

- The vehicle's mass is denoted as m and its moment of inertia with respect to the (body-fixed) vertical axis is denoted as I_z . The vehicle's center of mass G is located on the segment joining P_R to P_F , at a distance L_R from P_R and L_F from P_F .
- The longitudinal dynamics is neglected. More precisely, it is assumed that the traction force applied to the vehicle, in relation to the monitoring of longitudinal tire/ground contact forces, is controlled independently of the vehicle's lateral dynamics and that, as a result of this control, the longitudinal velocity of the vehicle expressed in body frame, i.e., $u_1 \cos \beta_r$, varies slowly so that its time-derivative

can be neglected in the calculus of the lateral dynamics.

- Lateral tire/ground contact forces, that are orthogonal to the wheels planes, are denoted as F_R and F_F respectively.
- The lateral component of the gravity force is denoted as F_G . This force applies at G and its magnitude is $mg \sin \alpha$ with α denoting the terrain slope angle in the lateral direction.

Application of Newton's law yields [49.15], after projection in the direction orthogonal to v_R ,

$$\dot{\beta}_R = \frac{1}{mu_1} \left[(F_R + mg \sin \alpha) \cos \beta_R + F_F \cos(\beta_R - \phi) - mL_R \ddot{\theta} \cos \beta_R \right] - \dot{\theta}$$

with F_F and F_R the (signed) intensity of the lateral forces \mathbf{F}_F and \mathbf{F}_R and

$$\ddot{\theta} = \frac{1}{I_z} (L_F F_F \cos \phi - L_R F_R) \quad (49.55)$$

From (49.53)

$$\tan(\phi + \beta_F) = \tan \beta_R - \frac{L \dot{\theta}}{u_1 \cos \beta_R}.$$

Differentiating this equation with respect to time and using the assumption that $u_1 \cos \beta_R$ is constant yields

$$\dot{\beta}_F = \cos^2(\phi + \beta_F) \left(\frac{\dot{\beta}_R}{\cos^2 \beta_R} - L \frac{\ddot{\theta}}{u_1 \cos \beta_R} \right) - \dot{\phi}.$$

The dynamics of the sliding angles is thus given by

$$\begin{cases} \dot{\beta}_R = \frac{1}{mu_1} \left[(F_R + mg \sin \alpha) \cos \beta_R + F_F \cos(\beta_R - \phi) - mL_R \ddot{\theta} \cos \beta_R \right] - \dot{\theta}, \\ \dot{\beta}_F = \cos^2(\phi + \beta_F) \left(\frac{\dot{\beta}_R}{\cos^2 \beta_R} - L \frac{\ddot{\theta}}{u_1 \cos \beta_R} \right) - \dot{\phi}. \end{cases} \quad (49.56)$$

Replacing the vehicle's angular acceleration $\ddot{\theta}$ by its expression (49.55), and $\dot{\theta}$, $\dot{\phi}$ by (49.53), one obtains expressions of the sliding angles dynamics in terms of ϕ , α , u_1 , u_2 , F_R , and F_F .

Tire/Ground Interaction Models for Lateral Forces Computation

In view of (49.56), knowledge of the lateral ground forces F_R and F_F is needed to calculate the evolution of the sliding angles and the vehicle's motion. In

Fig. 49.14 Lateral forces applying to a car-like vehicle

this respect, a model of tire/ground interactions is useful, in particular for simulation purposes. The Coulomb model, although very popular, does not allow one to describe the complexity of tire/ground interactions in a large operating domain. For this reason, other contact models have been proposed in the literature. For instance, the *Dahl* [49.16] and *LuGre* [49.17] models, even though they are not dedicated to tire/ground contact description, give a relationship between contact force and sliding velocity with a small number of parameters. They are used to describe a vehicle's dynamics in [49.18]. Of particular interest is the celebrated tire/ground contact model of Pacejka et al. [49.19], of which several versions depending on the application have been derived. A convenient model for mobile robot simulation and analysis is the so-called *magic formula* proposed in [49.20]. Alike other contact models, this formula expresses the lateral ground force in term of the sliding angle. It is defined as follows,

$$\begin{cases} F_* = D \sin \left[c \arctan(B[1 - E])\beta_* + \frac{E}{B} \arctan(B\beta_*) \right] \\ D = a_1 (F_z^*)^2 + a_2 F_z^* \\ E = a_6 (F_z^*)^2 + a_7 F_z^* + a_8 \\ B = \frac{a_3 \sin(a_4 \arctan(a_5 F_z^*))}{cD} \end{cases} \quad (49.57)$$

with $*$ $\in \{F, R\}$ used to denote either the front (F) or Rear (R) wheel, and F_z^* the corresponding tire load here defined as $\frac{L_*}{L}m$. The parameters a_i , $i \in [1, \dots, 8]$ and c are representative of the grip conditions and tire properties (pressure, contact patches). Table 49.1 shows typical values of these parameters for a vehicle moving on wet grass at a velocity of 2 m/s (Sect. 49.5.4 further on). Fig. 49.15 depicts the corresponding relation between the front lateral force F_F and the front sliding angle β_F . This relationship is symmetric with respect

Table 49.1 Parameters used for dynamic modelling

to the origin, is quasi linear for small angles, has an extremum near $\pm 10^\circ$, and involves a saturation for large sliding angles. The linear part of the function is often sufficient to account for slow to moderately fast motion in the case of good grip conditions, whereas its non-linear part becomes important when the vehicle moves on natural ground or at high speed with possibly large sliding angles.

Tire/ground contact models are necessary to describe the sliding angles' dynamics with some accuracy and are useful to evaluate the performance of control laws in simulation. The main drawback of these models is the large number of involved parameters and the difficulty to evaluate appropriate values in practical applications, since such values heavily depend on imprecisely known ground characteristics which, furthermore, may rapidly change along the vehicle's trajectory. For these reasons, previously evoked models may not be best suited for control design. In many cases, rather than trying to exploit a complete model involving unreliable and rapidly varying parameters it is preferable to use cruder models associated with an on-line estimation procedure. The control design proposed further on follows this latter avenue.

49.5.2 On-Line Estimation of Sliding Angles

As already mentioned, some knowledge of the sliding angles β_F and β_R is useful to precisely control the lateral distance d between the vehicle and the desired path. Since direct measurement of these angles via the use of dedicated sensors is quite difficult in practice, an alternative consists in designing an observer that produces on-line estimates of the sliding angles based on the measurement of the relative vehicle/path position and orientation. The underlying implicit (crude) model used

Fig. 49.15 Relationship between lateral force and sliding angle obtained using Pacejka Model

for the design of this observer is that the sliding angles do not change rapidly, as can be anticipated in common situations like driving along a road with a slowly varying curvature or following a straight line across a field with a constant slope. A solution of this type, exploiting also the vehicle's kinematic model (49.54), is proposed next.

Define $\xi = (d, \theta_e)^T$, $\beta = (\beta_F, \beta_R)^T$, and consider the function f defined by

$$f(\xi, \beta, \phi, c(s)) = \begin{pmatrix} \sin(\xi_2 + \beta_2) \\ \cos(\beta_2) \frac{\tan(\phi + \beta_1) - \tan(\beta_2)}{L} - \frac{c(s) \cos(\xi_2 + \beta_2)}{1 - \xi_1 c(s)} \end{pmatrix}.$$

From (49.54),

$$\dot{\xi} = u_1 f(\xi, \beta, \phi, c(s)). \quad (49.58)$$

Define an observer of the form

$$\begin{cases} \dot{\hat{\xi}} = u_1 f(\hat{\xi}, \hat{\beta}, \phi, c(s)) + \alpha_\xi, \\ \dot{\hat{\beta}} = \alpha_\beta. \end{cases} \quad (49.59)$$

The estimation error $(\tilde{\xi}, \tilde{\beta})^T = (\xi - \hat{\xi}, \beta - \hat{\beta})^T$ satisfies

$$\begin{cases} \dot{\tilde{\xi}} = u_1 [f(\xi, \beta, \phi, c(s)) - f(\hat{\xi}, \hat{\beta}, \phi, c(s))] - \alpha_\xi, \\ \dot{\tilde{\beta}} = -\alpha_\beta + \dot{\beta}. \end{cases} \quad (49.60)$$

The objective is to define the terms α_ξ and α_β so as to ensure the asymptotic stability of the origin of the above estimation error system when β is constant, i. e., when $\dot{\beta} = 0$, and thus the asymptotic convergence of the estimate $\hat{\beta}$ to β in this case. Furthermore, if β varies slowly the estimation error should remain small.

Proposition 49.6

Let

$$\begin{cases} \alpha_\xi = |u_1| K_1 \tilde{\xi} \\ \alpha_\beta = K_2 u_1 \left[\frac{\partial f}{\partial \beta}(\xi, \hat{\beta}, \phi, c(s)) \right]^T \tilde{\xi} \end{cases} \quad (49.61)$$

with K_1 a 2×2 positive definite matrix and K_2 a positive scalar. Assume that β is constant and that

- The variables $u_1, \xi, \phi, c(s), 1 - dc(s)$ are bounded, differentiable, and their time-derivatives are bounded.
- There exists $\tau > 0$ such that

$$|\phi + \beta_1|, |\beta_2|, |\xi_2 + \beta_2| \leq \pi/2 - \tau.$$

- The function u_1 is persistently exciting in the sense that there exist two constants $T, \delta > 0$ such that

$$\forall t, \int_t^{t+T} |u_1(s)| ds \geq \delta.$$

Then, the origin of system (49.60) is locally exponentially stable.

Sketch of Proof: From (49.61), the estimation error dynamics (49.60) can be written as

$$\begin{cases} \dot{\tilde{\xi}} = u_1 \left[\frac{\partial f}{\partial \beta}(\xi, \hat{\beta}, \phi, c(s)) \tilde{\beta} + O^2(\tilde{\beta}) \right] - |u_1| K_1 \tilde{\xi}, \\ \dot{\tilde{\beta}} = -K_2 u_1 \left[\frac{\partial f}{\partial \beta}(\xi, \hat{\beta}, \phi, c(s)) \right]^T \tilde{\xi}, \end{cases} \quad (49.62)$$

where $O^2(\tilde{\beta})$ denotes a second-order term in $\tilde{\beta}$ in a neighborhood of $\tilde{\beta} = 0$. Note that this term also depends on $\xi, \phi, c(s)$ and $1 - dc(s)$. The linearized system associated with system (49.62) is thus given by

$$\begin{cases} \dot{\tilde{\xi}} = u_1 \frac{\partial f}{\partial \beta}(\xi, \beta, \phi, c(s)) \tilde{\beta} - |u_1| K_1 \tilde{\xi}, \\ \dot{\tilde{\beta}} = -K_2 u_1 \left[\frac{\partial f}{\partial \beta}(\xi, \beta, \phi, c(s)) \right]^T \tilde{\xi}. \end{cases} \quad (49.63)$$

Consider the candidate Lyapunov function V defined by

$$V(\tilde{\xi}, \tilde{\beta}) = K_2 |\tilde{\xi}|^2 + |\tilde{\beta}|^2.$$

One verifies that the time-derivative of V along the solutions of system (49.63) satisfies

$$\dot{V} = -|u_1| K_2 \tilde{\xi}^T K_1 \tilde{\xi}.$$

Since K_1 is positive definite and K_2 is positive, V is decreasing. This ensures the stability of the origin $(\tilde{\xi}, \tilde{\beta}) = 0$. Using assumptions i) and ii) and the fact that the matrix $\partial f / \partial \beta(\xi, \beta, \phi, c(s))$ is invertible one can show, that the origin of system (49.63) is asymptotically stable. Assumption iii) implies that the origin is in fact exponentially stable. Using assumptions i) and ii) again, one shows that the origin of the original (nonlinear) system (49.62) is locally exponentially stable. ■

Proposition 49.6 calls for a few remarks. Although convergence of the estimation errors is proved in the case of constant sliding angles only, the observer can still provide a good estimate of β if $\dot{\beta}$ is *small*. For fast variations of β , estimation based on a dynamic model and IMU measurements (inertial measurement

unit) will usually provide better results [49.21]. Satisfaction of assumptions i) and ii) is strongly related to the choice of the controller used to determine the steering wheel angular velocity u_2 in (49.54). In this respect, let us recall that the separation principle, which allows one to design independently a feedback controller and an observer for a linear system with a guarantee of stability of the coupled system, is not systematically satisfied for nonlinear systems.

49.5.3 Feedback Laws for Path Following

The kinematic model (49.54) can be transformed into a chained system. This is a direct extension of the results of Sect. 49.4.1. More precisely, the change of coordinates and control variables $(s, d, \theta_e, \phi, u_1, u_2) \mapsto (z_1, z_2, z_3, z_4, v_1, v_2)$ defined by

$$\begin{aligned} (z_1, z_2, z_3, z_4) = & \\ \left\{ s, d, [1 - dc(s)] \tan(\theta_e + \beta_R), \right. & \\ -c(s)[1 - dc(s)] [1 + 2\tan^2(\theta_e + \beta_R)] & \\ -d \frac{\partial c}{\partial s} \tan(\theta_e + \beta_R) & \\ \left. + [1 - dc(s)]^2 \frac{\tan(\phi + \beta_F) - \tan \beta_R}{L} \frac{1 + \tan^2(\theta_e + \beta_R)}{\cos(\theta_e + \beta_R)} \right\}, & \\ (v_1, v_2) = (\dot{z}_1, \dot{z}_4) & \end{aligned}$$

transforms the model (49.54) of a car-like vehicle into a 4-D chained system.

Based on this transformation, Sect. 49.4 provides a feedback control solution v_2 to the path following problem. Since the relation between v_2 and the original control variable u_2 involves the sliding angles β_F and β_R , u_2 can be computed from the outputs $\hat{\beta}_F$, $\hat{\beta}_R$ of the observer proposed in the previous section.

In practice, preexisting low-level control loops may use the steering angle ϕ itself, rather than its time-derivative, as a control input. In this case the expression for the *desired* steering angle can be obtained by identifying the expression of θ_e in (49.54) with the one in (49.13), where u_2 is the feedback law deduced from the (chained-form) control law (49.27) of a unicycle-like robot. Further assuming that $c(s)$ is constant, one obtains the following expression

$$\begin{aligned} \phi_{\text{ref}} = \arctan \left[\tan(\hat{\beta}_R) \right. & \\ \left. + \frac{L}{\cos(\hat{\beta}_R)} \left(\frac{c(s) \cos \tilde{\theta}_2}{\kappa} + \frac{A \cos^3 \tilde{\theta}_2}{\kappa^2} \right) \right] - \hat{\beta}_F & \end{aligned} \quad (49.64)$$

with

$$\begin{cases} \tilde{\theta}_2 = \theta_e + \hat{\beta}_R \\ \kappa = 1 - c(s) d \\ A = -k_2 d - k_3 \kappa \text{sign}(u_1) \tan \tilde{\theta}_2 + c(s) \kappa \tan^2 \tilde{\theta}_2. \end{cases} \quad (49.65)$$

49.5.4 Path Following Illustrations in Low Grip Conditions

Simulation Results

The simulation results presented next have been obtained by using the kinematic and dynamic models (49.54) and (49.56) respectively, with the set of parameters for the tire/ground interaction specified in Table 49.1. The reference path, depicted on Fig. 49.16 in black plain line, is composed of two straight lines connected by a circular path with a radius of 13 m. The simulated grip conditions generate sliding along the circular part of the path. The transitions between this circular part and the straight lines yield transient errors due to the curvature discontinuity. The vehicle's velocity is 3 m/s.

The steering velocity u_2 is computed according to the simple proportional feedback law

$$u_2 = -k_\phi (\phi - \phi_{\text{ref}})$$

with ϕ_{ref} defined by (49.64) and the control gain $k_\phi = 12$ (settling time of 250 ms). The other control gains in (49.64) are defined as $(k_2, k_3) = (0.09, 0.6)$, yielding a settling distance of 12 m without overshoot. First,

Fig. 49.16 Reference path and trajectories in Cartesian plane

Fig. 49.17 Lateral tracking error (d)

the control law is applied with $(\hat{\beta}_F, \hat{\beta}_R) = (0, 0)$ (i. e., without considering sliding). The results are shown in blue on Figs. 49.16 and 49.17. Then, the control law is applied with $\hat{\beta}_F$ and $\hat{\beta}_R$ obtained via the observer (49.59)–(49.61), using for K_1 a diagonal matrix

Fig. 49.18 Comparison of estimated and *actual* sliding angles

with elements equal to 10 and 20 and the gain $K_2 = 10$. The results are shown in red. Fig. 49.17 clearly illustrates the reduction of lateral error resulting from the sliding angles estimation.

Fig.49.19a–c Path following with sliding effects for an autonomous off-road robot: (a) Reference trajectory in 3-D frame (b) Robot during autonomous tracking (c) Tracking errors (dashed: without sliding compensation, dash-dotted: with sliding estimation and compensation)

Performance of the proposed observer is illustrated on Fig. 49.18 with the *true* sliding angles (i. e., obtained from the simulated dynamics) in plain lines and the estimated angles in dashed lines. One can verify that the sliding angles are correctly estimated. In practice, using an observer allows one to also compensate for various unmodeled dynamics resulting, for instance, from imprecise knowledge of the vehicle's geometry (the distance L , for example) or from an unknown offset on the steering angle.

Experimental Results

Full scale experiments on natural terrain with the car-like vehicle of Fig. 49.19 are reported next and in  VIDEO 435. This mobile robot is equipped with a real time kinematics global positioning system (RTK-GPS) producing a ± 2 cm accurate absolute position measurement. The GPS antenna is located straight above the control point P_R . The reference path, consisting of a straight line perpendicular to the slope direction, has been previously recorded during a manual driving. The top left of Fig. 49.19 shows the recorded coordinates in x - y plane, and the z axis represents the absolute value of the lateral slope angle α . This angle progressively reaches the value of 10° at the curvilinear abscissa 27 m, and it subsequently rapidly increases up to about 18° .

As for the simulation results reported previously, the feedback control (49.64) was first applied with

$$\hat{\beta}_F = \hat{\beta}_R = 0$$

(i. e., without taking sliding into account), then with $\hat{\beta}_F, \hat{\beta}_R$ given by the observer. In both cases, control gains equal to these used in simulation have been used, i. e., $(k_2, k_3) = (0.09, 0.6)$. The vehicle's longitudinal velocity during experiments was 3 m/s. The bottom part of Fig. 49.19 shows the tracking error along the path with the blue dashed line corresponding to using $(\beta_F, \beta_R) = (0, 0)$ in the control law, and the red dashed-dotted line corresponding to the use of sliding angles estimated values.

These experimental results confirm the simulation ones reported before. The improvement in tracking accuracy resulting from the use of estimated sliding angles in the control law is clearly illustrated: the lateral error remains small (smaller than 0.25 m) all the time and it becomes negligible as soon as the terrain's slope is almost constant (beyond the curvilinear abscissa 30 m). This is consistent with the observer's stability and convergence analysis when the sliding angles are assumed constant.

49.6 Complementary Issues and Bibliographical Guide

49.6.1 General Trailer Systems

Most of the control design approaches here presented and illustrated for unicycle-like and car-like vehicles can be extended to the case of trains of vehicles composed of trailers hitched to a leading vehicle. In particular, the methods of Sect. 49.4 which are specific to nonholonomic systems can be extended to this case, provided that the kinematic equations of motion of the system can be transformed (at least semiglobally) into a chained system [49.6]. This basically requires that the hitch point of each trailer is located on the rear-wheel axle of the preceding vehicle [49.22]. For instance, the transformation to the chained form is not possible when there are two (or more) successive trailers with off-axle hitch points [49.23]. So-called *general trailer systems* (with off-axle hitch points) raise difficult control design issues, and the literature devoted to them is sparse. For this reason, and also because these systems are not met in applications as frequently as simpler vehicles, control methods specifically developed for them are not reported here. Nonetheless, a few

related references are given next. The path-following problem has been considered in, e.g., [49.24] for a system with two trailers and, more generally, in [49.25, Chap. 3] and [49.26] for an arbitrary number of trailers. To our knowledge, the problem of stabilizing nonstationary reference trajectories has not been addressed for these systems (except in the single trailer case for which the system can be transformed into the chained form [49.23, 27]). In fact, the explicit calculation of feasible trajectories joining a given configuration to another is already a very difficult problem, even in the absence of obstacles. As for the asymptotic stabilization of fixed configurations, the problem can (in theory) be solved by using existing general methods developed for the larger class of controllable driftless systems. However, the calculations associated with these methods quickly become intractable when the number of trailers increases. More specific and simpler ones have been proposed in [49.28], for an arbitrary number of trailers and the asymptotic stabilization of a reduced set of configurations, and in [49.29], in the case of two trailers and arbitrary fixed configurations.

49.6.2 Sensor-Based Motion Control

The control laws described in the present chapter, and their calculation, involve the online measurement, eventually complemented by the online estimation, of variables depending on the position of the vehicles in their environment. Measures can be acquired via the use of various sensors (odometry, GPS, proximity, vision, etc.). Usually, various treatments are applied to raw sensory data prior to computing the control variables themselves. For instance, noise filtering and state estimation are such basic operations, well documented in the automatic-control literature. Among all sensors, vision sensors play a particularly important role in robotic applications, due to the richness and versatility of the information which they provide. The combination of visual data with feedback control is often referred to as *visual servoing*. In Chap. 34, a certain number of visual servoing tasks are addressed, mostly in the context of manipulation and/or under the assumption that realizing the robot task is equivalent to controlling the pose of a camera mounted on an omnidirectional manipulator. In a certain number of cases, the concepts and methods described in this chapter can be adapted, without much effort, to the context of mobile robots. These cases basically correspond to the control methods adapted from robotic manipulation which are described in Sect. 49.3 of the present chapter. For instance, automatic driving via the control of the visually estimated lateral distance between a robotic vehicle and the side of a road, or car-platooning by controlling the frontal and lateral distances to a leading vehicle, can be addressed with the control techniques reported in Chap. 34. The reason is that it is possible to simply recast these techniques in the form of the control laws proposed in Sect. 49.3. However, there are also vision-based applications for nonholonomic mobile robots which cannot be solved by applying classical visual-servoing techniques. This is the case, for instance, of the task objectives addressed in Sect. 49.4, an example of which is the stabilization of the complete posture (i. e., position and orientation) of a nonholonomic vehicle at a desired one. Vision-based control problems of this type have been addressed in [49.11, 30].

49.6.3 Sliding Effects and Other Dynamical Issues

Results of Sect. 49.5 can be viewed as a first step to addressing dynamical issues associated with sliding effects. The kinematic control models (49.53)–(49.54) can be extended to other wheeled vehicles ([49.31] for the mobile robot classification proposed by [49.32] and [49.33] for a trailer system). On-line estimation of

sliding angles via an observer can also be achieved by exploiting the dynamics of these angles and making use of complementary measurements (from an IMU for example). A result in this direction is proposed in [49.21] where a model of sliding angle dynamics is used at the observer level, thus yielding a much more reactive estimation of these angles. Note that the kinematic control law of Sect. 49.5 may still be used in this case. When prior knowledge of the reference path is available, a predictive control strategy may also be adopted to reduce transient error effects associated with slow steering angle dynamics.

Various risks related to the vehicle's integrity when operating at high speed, like e.g., swing around or roll-over, were not addressed in this chapter. In [49.34] these issues are treated at the path planning level. Knowledge of the robot's dynamics can also be used to relate control inputs to a metrics measuring the importance of such risks in order to introduce constraints at the control level [49.35]. A multimodels approach (kinematic and dynamic) can be used to translate stability aspects into control constraints, for instance by defining a maximal admissible longitudinal velocity. A predictive control strategy may also help to limit the risk of roll-over, of steering saturation, or of swing around [49.36]. Finally, it is possible to take advantage of additional actuators, as in the case of four independent actuated wheels [49.37], or by using inclination actuators [49.38].

49.6.4 Bibliographical Guide

A few former surveys on the control of WMRs have been published. Let us mention [49.39–41], which contain chapters on the modeling and control issues. A detailed classification of kinematic and dynamic models for the different types of WMR structures, on which Chap. 24 is based, is provided in [49.32]. The use of the chain form to represent WMR equations has been proposed in [49.42], then generalized in [49.22].

Path following may have been the first mobile robot control problem addressed by researchers in robotics. Among the pioneering works, let us cite [49.43, 44]. Several results presented in the present chapter are based on [49.6, 45].

The problem of tracking admissible trajectories for unicycle-type and car-like vehicles is treated in the books [49.39–41], and also in numerous conference and journal papers. Several authors have addressed this problem by applying dynamic feedback linearization techniques. In this respect, one can consult [49.46–48], and [49.39, Chap. 8], for instance.

Numerous papers on the asymptotic stabilization of fixed configurations have been published. Among

them, [49.49] provides an early overview of feedback control techniques elaborated for this purpose, and also a list of references. The first result presenting a time-varying feedback solution to this problem, in the case of a unicycle-type vehicle, is in [49.4]. The conference paper [49.50] provides a survey on time-varying feedback stabilization, in the more general context of nonlinear control systems. More specific results, like Propositions 49.2 and 49.4, are given in [49.6, 7]. Other early results on the design of smooth time-varying feedbacks can be found in [49.51, 52], for example. Concerning continuous (but not Lipschitz-continuous) time-varying feedbacks yielding exponential convergence, one can consult [49.53]. Designs of hybrid discrete/continuous fixed-point sta-

bilizers can be found in [49.54–57], for instance. Discontinuous control design techniques are not addressed in the present chapter, but the interested reader will find examples of such feedbacks in [49.58, 59].

To our knowledge, the control approach presented in Sect. 49.4.6, which is based on the concept of transverse functions [49.9, 10], is the first attempt to address the problem of tracking *arbitrary* trajectories (i.e., not necessarily feasible for the controlled robot). Implementation issues and experimental results for this approach can be found in [49.11, 12]. An overview of trajectory tracking problems for wheeled mobile robots, with a detailed case study of car-like systems, is presented in [49.13].

50. Modeling and Control of Robots on Rough Terrain

Keiji Nagatani, Genya Ishigami, Yoshito Okada

In this chapter, we introduce modeling and control for wheeled mobile robots and tracked vehicles. The target environment is rough terrains, which includes both deformable soil and heaps of rubble. Therefore, the topics are roughly divided into two categories, wheeled robots on deformable soil and tracked vehicles on heaps of rubble.

After providing an overview of this area in Sect. 50.1, a modeling method of wheeled robots on a deformable terrain is introduced in Sect. 50.2. It is based on terramechanics, which is the study focusing on the mechanical properties of natural rough terrain and its response to off-road vehicle, specifically the interaction between wheel/track and soil. In Sect. 50.3, the control of wheeled robots is introduced. A wheeled robot often experiences wheel slippage as well as its sideslip while traversing rough terrain. Therefore, the basic approach in this section is to compensate the slip via steering and driving maneuvers. In the case of navigation on heaps of rubble, tracked vehicles have much advantage. To improve traversability in such challenging environments, some tracked vehicles are equipped with subtracks, and one kinematical modeling method of tracked vehicle on rough terrain is introduced in Sect. 50.4. In addition, stability analysis of such vehicles is introduced in Sect. 50.5. Based on such kinematical model and stability analysis, a sensor-based control of tracked vehicle on rough terrain is introduced in Sect. 50.6. Sect. 50.7 summarizes this chapter.

50.1 Overview

50.1.1 Modeling Deformable Terrain for Robots

The category of rough terrain includes a variety of ground conditions. In the case of weak and fine gravel, the motion of a wheeled mobile robot becomes relatively complicated because the interaction mechanics of the wheel in a rough terrain differs from that of an indoor robot on a flat surface; a wheel on gravel has multiple point contact, and a wheel on loose soil has a surface contact that deforms the soil around the wheel.

There has been a large amount of research on robot mobility analysis in the military community [50.1, 2]. These studies have primarily focused on empirical analyses of large vehicles (i. e., gross vehicle weights of several tons). The mobility analyses of small mobile robots that consider the interaction mechanics of a slipping wheel on rough terrain have also been investigated. Additionally, a multibody system simulation for the longitudinal slip of tires with respect to the tire–soil interaction has been demonstrated [50.3]. A dynamic interaction model, denoted as soil contact model (SCM), has been developed to provide the dynamics of a plastically deformable surface using an elevation grid, as well as to consider the multipass effect of wheels, shown in Fig. 50.1 [50.4]. Recently, multibody dynamics toolkit, such as Vortex (VIDEO 184), can be used to simulate terrain reaction forces for mobility analyses of mobile robots [50.5].

Recently, terramechanics [50.6] has been widely used in applications such as off-road UGVs (unmanned ground vehicles) [50.7, 8] and planetary rovers on Mars. A fundamental requirement for such off-road mobile robots is to maintain a traversing capability in rough

Fig. 50.1 Dynamics of a plastically deformable surface in consideration with the multipass effect of wheels (after [50.4])

terrain composed of loose sand, mud, pebbles, etc. One typical issue in such an environment is wheel slippage, which is generated because of the soil deformation at the wheel–terrain contact patch. Wheel slippage often degrades the mobility performance of the robot because some amount of tractive power from a driving actuator is consumed by the soil deformation. Furthermore, the wheel slippage induces vehicle sideslip, which is an additional disturbance for the motion control of a wheeled robot. Figure 50.2 shows one typical example of lateral- and side-slip situation of a wheeled mobile robot in rough terrain. One typical example of terramechanics-based modeling of rough terrain is described in Sect. 50.2. Recently, a study of terradynamics of legged locomotion was proposed for traversal in granular media in [50.9] and is shown in VIDEO 186.

50.1.2 Controlling Robots in Deformable Terrain

A wheeled robot often experiences wheel slippage as well as vehicle sideslip while traversing rough terrain. This degrades the motion control performance of the robot, i. e., a robot could deviate from the path to be followed or a wheel may get trapped in loose soil. Therefore, a control scheme that can derive the appropriate steering/driving maneuvers is necessary for a wheeled robot to achieve traversability on a rough terrain and to manage any slippage problems that may arise.

A large number of studies related to the path-following control of mobile robots have been published. General information on path-following issues can be obtained from [50.10–12]. Rezaei et al. investigated an online path-following strategy combined with a simultaneous localization and mapping (SLAM) algorithm for a car-like robot in outdoor environments [50.13].

Fig. 50.2 Lateral- and side-slip situation of wheeled mobile robot

Coelho and *Nunes* et al. proposed a Kalman-based active observer controller for the path-following of wheeled mobile robots [50.14]. *Helmick* et al. developed a path-following algorithm that included slip compensation by using visual odometry and a Kalman filter [50.15, 16]. The method was applied to the rocker-bogie configuration with six steerable wheels robot, shown in Fig. 50.3. In Sect. 50.3, a path-following control scheme for a four-wheeled mobile robot is introduced. The experimental validation of the control described in the section was reported in [50.17].

50.1.3 Modeling and Controlling Robots in Heaps of Rubble

In environments that involve heaps of rubble, such as an urban search and rescue situation, the approach for modeling and controlling robots is different from the afore mentioned methodology. To tackle such challenging environments, tracks are used to enhance the mobility of a robot in such environments because they have more contact with the terrain than wheels. Some tracked vehicles are equipped with active subtracks, and multitracks configuration enables the vehicle to get over relatively large steps. A typical geometrical model of tracked vehicles with subtracks is introduced in Sect. 50.4.

In case that the target rubble is stable, kinematic approaches are useful for navigation and control of the robot. In this case, stability analysis is very important. In classical stability analysis, the energy stability margin (**ESM**) proposed by *Messuri* and *Klein* was defined in terms of the potential energy of the robot [50.18]. *Hirose* assumed that increasing the robot's weight did not always contribute to its stability because it also increased the dynamic disturbance around its center of gravity. Therefore, he proposed the normalized **ESM**

(**NESM**), in which the robot's weight was normalized [50.19]. For this criterion, the **NESM** is used to evaluate the stability of a robot on the basis of the vertical distance between the initial and largest heights of the center of gravity during a rollover. Recently, *Tubouchi*'s group proposed a method to control tracked vehicles exposed to random steps [50.20] (Fig. 50.4). An artificial uneven environment is random steps, arranged with different lengths of squared timbers. It also appears in [VIDEO 189](#). This environment is used to evaluate the performance for urban search and rescue robots [50.21]. The basic objective is to maintain the maximal stability of the robot at every step of its path in the random step field. The earlier-given topic relating to stability analysis is introduced in Sect. 50.5. Another approach for stability analysis of tracked vehicles-based **NESM** was reported in [50.22].

To evaluate the stability of vehicles, terrain detection is an important technology. Therefore, many robotics researchers have focused on the terrain mapping, particularly based on the **SLAM**, described in Chap. 46, and machine learning. **LIDAR** (light detection and ranging) and stereo cameras are widely used for the terrain mapping (Sect. 22.3). *Vandapel* et al. proposed a classification method of three-dimensional (3-D) point cloud data on the basis of its geometrical features [50.23], and *Lacaze* et al. demonstrated a method of finding a path in heavy grasses [50.25]. To improve the **LIDAR**-based mapping, *Ohno* et al. proposed a method to obtain thin objects such as nets, poles, and wires [50.26]. Figure 50.5 shows a mapping result at an outdoor rough terrain.

If the rubble is unstable, modeling the machine-rubble interaction is very complicated. One challenging

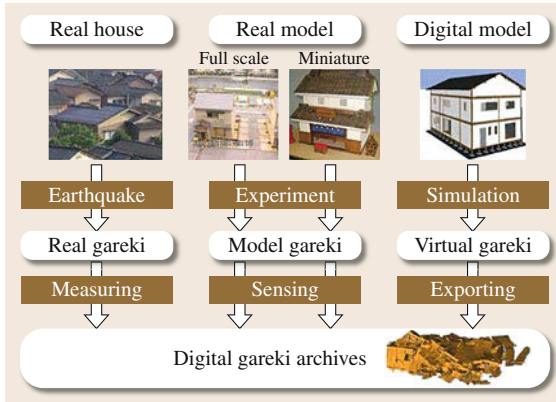

Fig. 50.6 Approaches for gareki data acquisition (after [50.24])

approach to modeling rubble is called gareki (rubble in Japanese) engineering [50.27, 28]. The model includes not only the structure data, but also the internal force of each gareki element. To obtain the data, they proposed to use information about the following, as shown in Fig. 50.6: (1) a real-collapsed building, (2) artificial full- and miniature-scale col-

lapsed buildings, and (3) a simulated virtual digital building. Their research aims to eventually apply the gareki model for the control of mobile robots and rescue missions.

The sensor-based method is another approach for controlling robots in unstable rubbles. Such robots often have multiple tracks connected by joints to maneuver over natural/artificial steps, bumps, and stairs. Some are equipped with passive joints [50.29], but many are equipped with active joints [50.30]. Multitrack configurations enable the vehicle to maneuver over a step that is higher than the radius of the tracks. To enable such motion, a sensor-based method is proposed to control the multitracks. The robot moves and detects the surface shape of the ground continuously, and it changes the configuration of the subtracks based on the surface information. Once the surface of the ground is deformed by the traversal of the robot, the subtracks adapt quickly. A representative example for the control of robots in unstable rubble is shown in Sect. 50.6. Another sensor-based approach is to use force-feedback from contact points. Inoue et al., embedded force sensors in their subtracks to obtain the contact force, and changed the configuration of the subtracks [50.31].

50.2 Modeling of Wheeled Robot in Rough Terrain

This section introduces a mechanics of wheeled mobile robot in rough terrain, particularly focusing on a modeling of wheel–terrain interaction.

50.2.1 Dynamics of Mobile Robots

Figure 50.7 depicts a schematic illustration of a dynamic model for a wheeled mobile robot. The robot is modeled as an articulated multibody system. The equation of motion for the robot is numerically given by

$$\mathbf{H} \begin{pmatrix} \dot{\mathbf{V}}_b \\ \ddot{\mathbf{q}} \end{pmatrix} + \mathbf{C} + \mathbf{G} = \begin{pmatrix} \mathcal{F}_b \\ \boldsymbol{\tau} \end{pmatrix} + \mathbf{J}^T \mathcal{F}_e, \quad (50.1)$$

where the symbols have the following meanings: \mathbf{H} : inertia matrices composed of multibody of the robot, \mathbf{C} : velocity depending term, \mathbf{G} : gravity term, \mathcal{V}_b : translational and angular velocities of the vehicle, \mathbf{q} : joint angles (such as wheel rotation and steering angles), \mathcal{F}_b : forces and moments at the centroid of the vehicle body, $\boldsymbol{\tau}$: torques acting at each joint (driving/steering torques), \mathbf{J} : Jacobian matrix, \mathcal{F}_e : external forces and moments acting at the centroid of each wheel, namely

$$f_{ij} (i = \{r, l\}, j = \{r, m, f\}).$$

The dynamic motion of the robot with given traveling and steering maneuvers are numerically obtained

by successively solving (50.1). Here, a key approach for the dynamic model is to incorporate a well-defined contact model into the equation of motion in order to calculate the external forces and torques at the contact patch between the wheel and terrain. Some recent works have reported dynamic simulation tools combined with the terramechanics wheel model: for example, [50.32, 33] for the NASA's rovers, and [50.4, 34] for the ExoMars.

50.2.2 Wheel–Terrain Interaction Mechanics

Terramechanics is a study focusing on the mechanical properties of natural rough terrain and its response to off-road vehicle, specifically the interaction between wheel/track and soil. In 1960s, *Bekker* developed a classical terramechanics with many of the key concepts related to vehicle–terrain response, such as a well-known pressure-sinkage equation and shear stress model [50.35, 36]. Wong developed a comprehensive procedure for predicting the performance of both driven and towed wheels [50.37–39]. The procedure calculates the wheel mechanics with applying the stress distribution model beneath the wheel.

Terramechanics-based approach for vehicle–terrain mechanics includes mainly three methodologies [50.40, 41]: (1) Analytical approach, (2) empirical approach, and (3) numerical approach.

The analytical approach is based on a theoretical model for vehicle–terrain interactions along with experimental model validation. The empirical method is to utilize a practical measurement of soil strength

Fig. 50.7 Dynamic model of wheeled mobile robot

by a specialized apparatus in order to estimate vehicle traversability on weak/rough terrain. The numerical method includes the finite element method (FEM) and discrete element method (DEM) that models soils as vast numbers of multiple particles and simulates each particle's behavior while accounting vehicle–terrain interaction [50.42–44].

This subsection focuses on the analytical method and introduces a typical interaction model of rigid wheel on deformable terrain (Fig. 50.8). It should be noted that Chap. 55.3.13 also addresses the wheel traction mechanics in detail, and therefore, the following subsection recalls some key equations in order to dis-

Fig. 50.8 Wheel–terrain contact model

(after [50.48])

cuss a wheel traction characteristics on rough terrain, soil parameter identification, and model uncertainty.

Wheel Slippage

Wheel slippage is generally observed when a robot travels on loose soil. Also, the wheel will slip in the lateral direction while the robot steering or traversing on sloped terrain. The slip ratio (i. e., slip in the longitudinal direction of wheel travel) is defined as a function of the longitudinal traveling velocity of the wheel v_x and the circumferential velocity of the wheel $r\omega$, where r is the wheel radius and ω represents the angular velocity of the wheel [50.37]

$$s = \begin{cases} (r\omega - v_x)/r\omega & (|r\omega| \geq |v_x| : \text{driving}) , \\ (r\omega - v_x)/v_x & (|r\omega| < |v_x| : \text{braking}) . \end{cases} \quad (50.2)$$

The slip ratio assumes a value in the range from -1 to 1 .

The slip in the lateral direction of the wheel is expressed by the slip angle β , which is defined as a function of v_x and the lateral traveling velocity v_y , as

$$\beta = \begin{cases} \tan^{-1}(v_y/v_x) & (v_x \neq 0) , \\ \text{sgn}(v_y) \cdot \pi/2 & (v_x = 0) . \end{cases} \quad (50.3)$$

Wheel Traction Forces

The wheel–terrain contact forces, including the drawbar pull F_x , side force F_y , vertical force F_z , and resistance torque T , are calculated as the integral of the normal

and shear stresses from the entry angle θ_f and the exit angle θ_r [50.38, 48]

$$F_x = rb \int_{\theta_r}^{\theta_f} \{ \tau_x(\theta) \cos \theta - \sigma(\theta) \sin \theta \} d\theta , \quad (50.4)$$

$$F_y = \int_{\theta_r}^{\theta_f} [rb\tau_y(\theta) + R_b \{ r - z(\theta) \cos \theta \}] d\theta , \quad (50.5)$$

$$F_z = rb \int_{\theta_r}^{\theta_f} \{ \tau_x(\theta) \sin \theta + \sigma(\theta) \cos \theta \} d\theta , \quad (50.6)$$

$$T_x = r^2 b \int_{\theta_r}^{\theta_f} \tau_x(\theta) d\theta , \quad (50.7)$$

where $\sigma(\theta)$ is the normal stress, $\tau_x(\theta)$ and $\tau_y(\theta)$ are the shear stresses in the longitudinal or lateral direction. $z(\theta)$ is the wheel sinkage at an angle of θ , b is the wheel width, and R_b is the bulldozing resistance generated on a side wall of the wheel.

Experimental Validation

An experimental validation of the afore mentioned wheel–terrain interaction model is performed by the use of a single wheel test bed (Fig. 50.9), with varied state parameters such as soil or wheel slip conditions. A carriage velocity controlled relative to a wheel velocity realizes a wheel slip (or traction load) while measuring wheel traction forces, wheel

sinkage, and others. Experimental data obtained from the test bed are then compared with the values obtained from numerical simulation of the wheel traction model.

50.2.3 Wheel Traction Performance

The wheel–terrain model can be exploited for an evaluation of the mobility performance of a wheeled robot (i.e., traversability on sloped or deformable terrain [50.49, 50]). Such mobility evaluation technique is further valuable for the mobility system design in order to find a feasible wheel/track design that maximizes the traction performance for off-road locomotion under some specific constraints [50.46, 47, 51].

Ishigami et al. proposed a wheel traction diagram called a thrust–cornering characteristic diagram that determines the slope traversal criteria with respect to wheel slip conditions [50.17]. Figure 50.10 illustrates the relationship between the thrust and cornering forces of wheel on rough terrain, with varied slip ratios/slip angles. The thrust and cornering forces F_c and F_T are obtained by calculating the drawbar pull and side force

$$F_c = F_x \sin \beta + F_y \cos \beta, \quad (50.8)$$

$$F_T = F_x \cos \beta - F_y \sin \beta. \quad (50.9)$$

Considering the slope traversal scenario as shown in Fig. 50.11, the thrust–cornering characteristic diagram can draw the criteria with a minimum cornering force and thrust force required for a slope traversal: Case 1 as a traversal and uphill traveling, Case 2 as a straight-line traversal, and Case 3 as a traversal and downhill traveling. In addition, a robot decelerates or cannot move forward due to its negative thrust force. This diagram, for example, indicates that the slip ratio must exceed 0.6 in order to generate positive thrust force, and also, the cornering force varies primarily with the slip angle. Therefore, the diagram can determine the slope traversability on the basis of the corresponding slip-page, indicated by several characteristic curves on the diagram.

50.2.4 Model Uncertainty and Soil Parameter Identification

It should be noted that the classical terramechanics model has primarily developed for an application for large-heavy vehicles (hundreds/thousands kg weight). Therefore, several assumptions that may cause an inaccurate calculation of wheel traction performance of

the classical model would be omitted while exploiting the classical model to an analysis of small lightweight robot, resulting in an inaccurate calculation of wheel traction performance. The error due to the inadequate assumptions for the small-lightweight robot can be addressed by the following approaches: model improvement and uncertainty analysis of model parameters. It should be noted that the Bekker's pressure-sinkage model is assumed that the contact patch of wheel on deformable soil (circumferential section) is discretized

Fig. 50.10 Thrust–cornering characteristic diagram

Fig. 50.11 Force balance on slope traversal

as a series of consecutive flat plate; however, *Bekker* noted [50.36]:

Predictions for wheels smaller than 20 inches in diameter become less accurate as wheel diameter decreases, because the sharp curvature of the loading area was neither considered in its entirety nor is it reflected in bevameter tests.

Also another research reported that the assumptions provide inaccurate prediction for vehicles with wheels diameter less than about 50 cm (approx.) and normal loading less than 45 N (approx.) [50.36].

Some researchers have tried to update/improve the classical terramechanics model that can be successfully applied to relatively light weight vehicles: For example, *Nagatani* et al. developed a direct measurement device for the normal stress distribution [50.52]. A wheel diameter dependent pressure-sinkage model has been proposed by [50.53]. *Senatore* and *Iagnemma* proposed

an improved approach for the calculation of shear deformation modulus [50.54].

Model parameters in the wheel–terrain interaction related to the soil properties are subject to uncertainties since their values would stochastically vary with location. Several researches have addressed the soil parameter identification: an on-line terrain parameter estimator with simplifying classical terramechanics equations was proposed by [50.55]; a modified nonlinear wheel–terrain interaction model for an identification of pressure-sinkage coefficient, internal friction angle, and shear deformation modulus [50.56]. Some recent works have also attempted to predict rover mobility even in uncertain conditions: a learning-based approach for slip-prediction and traversability analysis of a wheeled robot [50.57]; and a statistical method for mobility prediction of a robot with taking into account of terrain uncertainty [50.58].

50.3 Control of Wheeled Robot in Rough Terrain

This section introduces a control scheme for the wheeled robot that compensates wheel-and-vehicle slippages while following a given path is described.

A wheeled robot often experiences wheel slippages as well as vehicle sideslip while traversing in rough terrain, which degrades a performance of a motion control of the robot: i.e., a robot will deviate from a path to be followed, or a wheel might get stuck into loose soil. Therefore, a control scheme that can derive appropriate steering/driving maneuvers is necessary for a wheeled robot to achieve a rough terrain traverse and to manage any slippage problems.

A significant number of studies related to the path following control of mobile robot have been published. A general note for path following issues can be seen in [50.10–12]. *Rezaei* et al. investigated an online path following strategy combined with a simultaneous localization and mapping (SLAM) algorithm for a car-like robot in outdoor environments [50.13]. *Coelho* and

Nunes et al. proposed a Kalman-based active observer controller for the path following of wheeled mobile robots [50.14].

As noted before, a key issue of the path following on rough terrain is to compensate wheel-and-vehicle slippage. This subsection briefly introduces a slip-compensated path follower along with a derivation for steering and driving maneuvers for path following [50.15–17] which is shown in [VIDEO 188](#).

50.3.1 Slip-Compensated Path Follower

A two-dimensional path-following problem of a mobile robot is shown in Fig. 50.12. Here, a path following control generally performs to let the vehicle velocity v_0 coincide with the tangent of a given path such that the distance and orientation errors decrease to zero. However, once the vehicle experiences a sideslip with a certain amount of slip angle β_0 , the vehicle has an additional orientation error of β_0 even

Fig. 50.12a,b Path following problem without (a) and with (b) slip angle of vehicle

when the vector of vehicle velocity completely follows the path (Fig. 50.12b).

The path follower basically derives a commanded robot velocity vector $(\dot{x}_{\text{cmd}}, \dot{y}_{\text{cmd}}, \dot{\theta}_{\text{cmd}})$ while the robot position (x_0, y_0, θ_0) and a reference path vector (x_p, y_p) are given. The slip-compensated path follower described here consists of two algorithms to achieve a path following task through high-slip environments.

First, the carrot heading algorithm determines the heading error of the robot θ_e , which is an angle calculated from the intersection of a circle centered on the robot coordinate with the desired path (Fig. 50.13):

$$\theta_e = \theta_d - \theta_0 \quad (50.10)$$

Here, θ_d is the desired heading angle which is a tangent angle on the intersection point and θ_0 is the robot heading angle. A large radius of the circle will generate a smooth motion of the robot while neglect a small feature of the path. A small radius will reduce the total path following error, but requires frequent heading changes for small path errors.

Once the heading error is determined, the slip-compensated path following algorithm executes the heading controller that calculates the commanded yaw rate of the robot $\dot{\theta}_{\text{cmd}}$ from the heading error θ_e and the yaw slip rate $\dot{\beta}_0$

$$\dot{\theta}_{\text{cmd}} = \frac{(K_1 \cdot \theta_e + K_2 \cdot \dot{\beta}_0)}{T_s}, \quad (50.11)$$

where K_1 and K_2 are the tuned controller gains, and T_s is the sampling period.

Note that the command for the linear velocity \dot{x}_{cmd} and \dot{y}_{cmd} are closely related to the maximum speed of the driving motors and the desired heading angle $\dot{\theta}_{\text{cmd}}$. Practically, these commands are accomplished by actuators of the robotic mobility system, namely steering and driving mechanisms. The following subsection describes the derivation of those steering and driving maneuvers that satisfies the heading controller command $\dot{\theta}_{\text{cmd}}$ as defined in (50.11).

50.3.2 Steering and Driving Maneuvers

Here, a nonholonomic kinematic model of a four-wheeled mobile robot with each wheel being independently steerable is considered. Figure 50.14 illustrates a two-dimensional kinematic model of the mobile robot having the slip angle of the vehicle β_0 and lateral wheel slippage β_i (the subscript i denotes the wheel identification number, $i = 1, \dots, 4$ in this

case). The dimension of the rover is defined by l_f , l_r , d_R , and d_L . The position and orientation of the vehicle are defined as (x_0, y_0, θ_0) , and the position of each wheel is defined as (x_i, y_i) . In this model, the following assumptions are considered: the distance between the wheels is constant, and the steering axle of each wheel is perpendicular to the terrain surface.

The nonholonomic constraints of the mobile robot are defined by the following equations, with taking the lateral slips of wheels and that of vehicle into account

$$\begin{aligned} \dot{x}_0 \sin \phi_0 - \dot{y}_0 \cos \phi_0 &= 0, \\ \dot{x}_i \sin \phi_i - \dot{y}_i \cos \phi_i &= 0, \end{aligned} \quad (50.12)$$

where $\phi_0 = \theta_0 + \beta_0$ and $\phi_i = \theta_0 + \delta_i + \beta_i$. The geometric constraints between each wheel and the centroid of

Fig. 50.13 Path following with carrot heading calculation

Fig. 50.14 Kinematic model of four-wheeled rover with wheel/vehicle slips

the vehicle are written as

$$\begin{cases} x_1 = x_0 + l_f \cos \theta_0 - d_L \sin \theta_0 \\ x_2 = x_0 - l_r \cos \theta_0 - d_L \sin \theta_0 \\ x_3 = x_0 - l_r \cos \theta_0 + d_R \sin \theta_0 \\ x_4 = x_0 + l_f \cos \theta_0 + d_R \sin \theta_0 \end{cases} \rightarrow x_i = x_0 + X_i, \quad (50.13)$$

$$\begin{cases} y_1 = y_0 + l_f \sin \theta_0 + d_L \cos \theta_0 \\ y_2 = y_0 - l_r \sin \theta_0 + d_L \cos \theta_0 \\ y_3 = y_0 - l_r \sin \theta_0 - d_R \cos \theta_0 \\ y_4 = y_0 + l_f \sin \theta_0 - d_R \cos \theta_0 \end{cases} \rightarrow y_i = y_0 + Y_i. \quad (50.14)$$

Given the desired heading angle $\theta_0 = \theta_d$ and desired linear velocity v_d , the desired steering angle δ_{di} that satisfies the path following control as well as the slip compensation is obtained as follows: first, transform (50.12)

$$\delta_{di} = \tan^{-1} (\dot{y}_i / \dot{x}_i) - \theta_d - \beta_i. \quad (50.15)$$

Subsequently, substituting (50.13) and (50.14) into (50.15), the desired steering angle is determined as follows

$$\delta_{di} = \tan^{-1} \left(\frac{v_d \sin \theta_d - \dot{Y}_i(\dot{\theta}_d)}{v_d \cos \theta_d - \dot{X}_i(\dot{\theta}_{cmd})} \right) - \theta_d - \beta_i. \quad (50.16)$$

The desired yaw rate $\dot{\theta}_{cmd}$ is given from (50.11).

The driving maneuver is practically executed by the wheel angular velocity of the robot. From Fig. 50.14,

the wheel linear velocity v_i is given as

$$v_i = r\omega_i / \cos \beta_i, \quad (50.17)$$

v_i is also expressed by \dot{x}_i or \dot{y}_i

$$v_i = \dot{x}_i / \cos \phi_i = \dot{y}_i / \sin \phi_i. \quad (50.18)$$

Substituting (50.13) or (50.14) into the above equations, the desired wheel angular velocity ω_{di} can be obtained

$$\omega_{di} = \begin{cases} \left(v_d \cos \theta_d + \dot{X}_i(\dot{\theta}_{cmd}) \right) \cos \beta_i / r \cos \phi_i \\ \quad (\theta_d \leq \pi/4), \\ \left(v_d \sin \theta_d + \dot{Y}_i(\dot{\theta}_{cmd}) \right) \cos \beta_i / r \sin \phi_i \\ \quad (\theta_d \geq \pi/4). \end{cases} \quad (50.19)$$

Position and orientation errors relative to a desired path should be accurately determined for deriving the control input as well as calculating the corresponding steering and driving maneuvers. A visual odometry method is of promising technique for such accurate measurement of position, orientation, velocity, and slip-page, and also it is sufficiently robust for loose sandy terrain.

The visual odometry estimates the traveling velocity of the vehicle based on the optical flow vectors obtained from the time-consecutive images taken by an onboard camera(s). Integrating the velocity estimates with inertial measurement unit (IMU) readouts or stereo images for pose estimation provides an accurate estimation of the six degrees of freedom of the rover motion.

50.4 Modeling of Tracked Vehicle on Rough Terrain

Tracks are one of typical mechanism that can enhance the mobility of a robot on rough terrain because they can have contacts between the terrain more widely than wheels. Thus, many types of robots which are required to maneuver rough terrain such as military and search-and-rescue robots have been equipped with tracks.

Some tracked vehicles often have multiple tracks connected by joints to maneuver natural/artificial steps, bumps and stairs. Some are equipped with passive joints, but many are equipped with active joints. Multitracks configuration enables the vehicle to get over a step which is higher than the radius of the tracks.

It should be noted that many tracked vehicles are intended to maneuver the unknown rough terrain con-

sisted of rubbles, rocks, concrete, and woods. Because such types of terrain are nonuniform unlike fine soil discussed in the Sect. 50.2, to dynamically model them is obviously difficult. In other words, we can easily sense the shape of the terrain, but dynamic parameters as well as center of gravity (COG), weight or stiffness of terrain cluster.

Thus, to geometrically consider the interaction between tracks and terrain is a reasonable approach. In this section, a geometrical model of a contact between a track and the terrain surface is introduced. The analysis includes (1) a parameterization of a generic shaped track, (2) contacts between the track and a single point in the terrain surface, and (3) contacts between the track and the terrain surface represented by a point cloud.

50.4.1 Parameterization of a Track

The geometry of a generic-shaped track is the key issue that should be discussed for modeling a tracked vehicle on rough terrain. In this section, we introduce a parameterization of the shape of a generic track.

As shown in Fig. 50.15, a generic track can be parameterized by the radius of the first and the second pulleys, R and r respectively, and the distance between the centers of the pulleys L .

In addition, let us embed the coordinate frame; its origin is at the center of the adjacent track and the x axis is along the center line of the adjacent track. The relative pose of the track respect to the adjacent track can be parameterized by the distance between the origin and the center of the first pulley, and the angle of the joint that connects the tracks θ .

50.4.2 Contact with a Single Point in the Terrain Surface

To discuss contacts between a track and a single point in the terrain surface is a good entrance to understand it between a track and the whole terrain surface. In the following sections, we geometrically describe the former contacts with the parameters of the track defined in the previous section.

As shown in Fig. 50.16, a track generally has four sections that can contact with the terrain surface; since it is tracked, it comprises a round and straight sections. Moreover, it can be in two states, namely, folded and spread states. When the track is in the spread state, side-S supports the robot; on the other hand, when it is in the folded state, side-F is in contact with the terrain. We call the case where side-S is in contact with the ground as the *spreading mode* and the case where side-F is in contact with the ground as the *folding mode*.

Fig. 50.15 Example of geometrical analysis contact between track and single point on the terrain surface

In addition, we have assumed the pose of the track to be 0° when its straight section on side-S is in contact with the flat surface; we have also assumed the direction in which the track lifts its second pulley from 0° to be positive.

The geometrical relationship between the contact point and pose of the track is summarized in Table 50.1. For example, in the case of the spreading mode and the contact on the straight section (Fig. 50.15), we can derive the following equation according to the geometry of the track contacting with the surface

$$\begin{aligned}\theta_{\text{contact}} &= \theta_1 + \theta_2 \\ &= \tan^{-1} \frac{z}{x - x_{\text{support}}} \\ &\quad + \sin^{-1} \frac{r}{\sqrt{(x - x_{\text{support}})^2 + z^2}}.\end{aligned}\quad (50.20)$$

50.4.3 Contact with the Terrain Surface Represented by a Point Cloud

Now we are well prepared to geometrically understand contacts between the track and the terrain surface. In this section, we describe those contacts by iterating a point cloud that represents the terrain surface.

Let the shape of the terrain surface be represented by a set of points $\{u_1, u_2, \dots, u_n\}$. Then, the contact angle of the track with the surface is determined using the following equation

$$\theta_{\text{ref}} = \begin{cases} \min(\theta_{\text{contact},1}, \dots, \theta_{\text{contact},n}): \\ \text{in spreading mode,} \\ \max(\theta_{\text{contact},1}, \dots, \theta_{\text{contact},n}): \\ \text{in folding mode.} \end{cases}\quad (50.21)$$

To calculate a contact angle of the track with a single point in the terrain surface, we need to determine which section and which side of the track makes the contact.

Fig. 50.16 Generic-shaped track consisted of straight and round sections

Table 50.1 Geometric-based contact angle of subtrack

Section		θ_{contact}
Spreading	Straight	$\tan^{-1} \frac{z}{x - x_{\text{support}}} + \sin^{-1} \frac{r}{\sqrt{(x - x_{\text{support}})^2 + z^2}}$
	Round	$\cos^{-1} \frac{d^2 + L^2 - R^2}{2Ld} + \tan^{-1} \frac{z}{x - x_{\text{support}}} - \sin^{-1} \frac{R - r}{L}$
Folding	Straight	$\tan^{-1} \frac{z}{x - x_{\text{support}}} - \sin^{-1} \frac{r}{\sqrt{(x - x_{\text{support}})^2 + z^2}} - 2 \sin^{-1} \frac{R - r}{L}$
	Round	$\tan^{-1} \frac{z}{x - x_{\text{support}}} - \sin^{-1} \frac{R - r}{L} - \cos^{-1} \frac{d^2 + L^2 - R^2}{2Ld}$

The type of the section can be determined by checking the distance between the center of the first pulley and the point; if $d < \sqrt{L^2 + R^2}$ the straight section makes the contact, else the round section does. On the other hand, the side will be determined by the choice of the application.

Now we understand a geometric model which describes contacts between the tracked vehicle consisted of multiple tracks and the free-formed terrain surface whose shape is represented as a point cloud. In the following subsection, we introduce an application example utilizing the contact model.

50.5 Stability Analysis of Tracked Vehicles

As shown in the previous sections, it is hardly possible to build an indentation model of a rough terrain consisted of rubbles. Thus, in this research domain, stability criteria based only on geometrical parameters are often used to evaluate pose of the tracked vehicle on the rough terrain.

This section introduces two typical stability criteria which have been adopted for tracked vehicles; (1)

support polygon and (2) normalized energy stability margin.

The support polygon is a simple and reasonable criterion to determine whether an object on a surface is statically stable. The support polygon for the tracked vehicle is equal to the horizontal projection of the convex hull of all the contact points between the tracks and the terrain. With this support polygon, we can consider

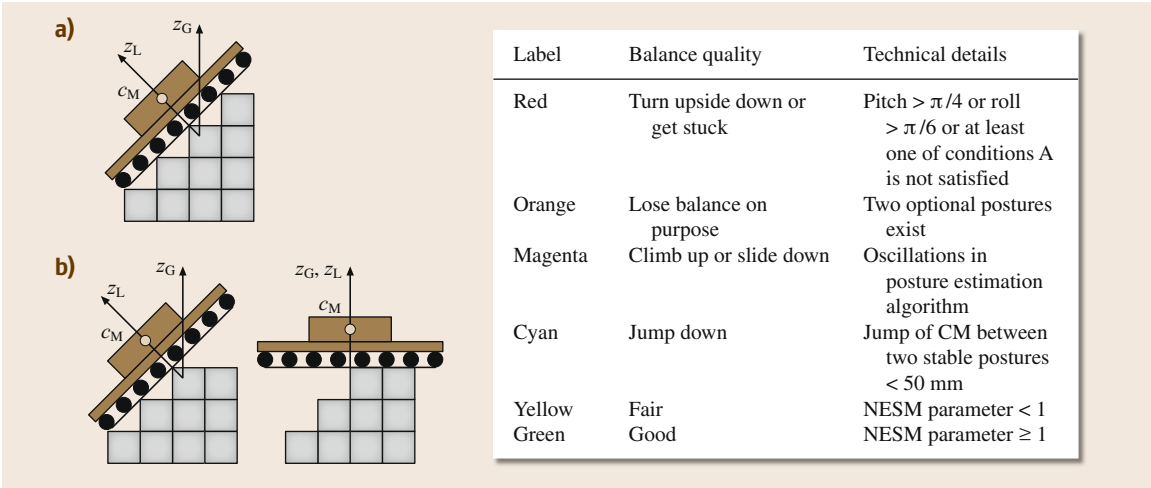

Fig.50.17a,b Example of stability analysis of tracked vehicle on a rough terrain based on support polygon and NESM (after [50.20]); (a) Stable posture corresponding to green label in table. (b) Unstable posture corresponding to orange label in table

that the vehicle is statically stable when it contains the projection of the vehicle's center of gravity.

Another stability criterion is the normalized energy stability margin, or **NESM**, proposed by Hirose. The **NESM** is a criterion that is used to evaluate the stability of a robot on the basis of the vertical distance between the initial position of its center of gravity and its highest position during tumbling. Although it is mainly used for walking robots, its evaluation only requires the positions of contact points with the ground and the center of gravity of the robot. In other words, there is no concep-

tual difference if this criterion is applied to the stability of tracked vehicles.

One typical application of stability criteria for the tracked vehicle is to rank possible path in a navigation. For example, Magid proposed a rating method for possible paths based on stability analysis utilizing the support polygon and **NESM**. This method evaluates the stability of each adjacent grid of the current position of the vehicle; paths to grids on which the support polygon condition is violated are denied. Then survived paths are ranked utilizing the **NESM** (Fig. 50.17).

50.6 Control of Tracked Vehicle on Rough Terrain

In this section, an approach for the autonomous control of active joints in a tracked vehicle with multiple tracks is introduced. As shown in the previous subsections, the geometric model of the tracked vehicle gives the pose of each track, which makes contact with the rough terrain on the basis of the shape of the terrain surface near the vehicle. The autonomous control utilizes the geometric model to determine the desired angles of the active joints between the tracks to perform a smooth maneuver on an unknown rough terrain.

Tracked vehicles with multiple tracks and joints typically have better locomotion than single-tracked vehicles. This is because one can change the pose of a track by actuating an adequate joint to negotiate bumps or steps in a rough terrain. Some multi-tracked vehicles are equipped with a single-degree-of-freedom (1-DOF) tracked arms, often called subtracks, and the others are snake shaped.

However, multitracked vehicles are difficult to control manually because of their multiple degrees of

freedom. For military and search-and-rescue robots in particular, which are likely to be teleoperated on an unknown rough terrain with limited camera views, it is quite difficult to control all of their **DOFs** manually.

In the rest of this section, an approach for the autonomous control of active subtracks on the basis of the geometric model of a multitracked vehicle is introduced. In the control algorithm, the geometric model automatically determines the desired poses of active joints, which support subtracks on the basis of the terrain shape obtained in real time.

The multitracked vehicle Kenaf, which has autonomous subtrack control, is shown in Fig. 50.18. Kenaf has two main tracks covering its main body and four subtracks actuated by 1-DOF joints on each corner of the main body. It has 6-DOFs in total: 4-DOFs corresponding to joints supporting the subtracks, 1-DOF corresponding to the one main track and two subtrack belts on the right, and 1-DOF corresponding to the one main track and two subtrack belts on the left.

In addition, Kenaf is equipped with three **LIDAR** sensors, one on the front, one on the right side, and one on the left side of the main body, to obtain data on the shape of the terrain online. Scans from **LIDARs** are integrated to estimate the three-dimensional shape of the terrain near the vehicle. The aforementioned approach for autonomous control of active subtracks are described in [50.59].

Figure 50.19 shows the flowchart of the algorithm for the autonomous subtrack control, and its actual motions can be seen in [VIDEO 190](#) and [VIDEO 191](#). The control algorithm is divided into six steps and summarized as follows:

1. Slices of the shape of the terrain around the robot are first obtained from the **LIDAR** sensors attached

Fig. 50.18 Tracked vehicle Kenaf equipped with four subtracks enhancing mobility and three **LIDAR** sensors sensing shape of terrain

- to the robot body and the three-dimensional terrain shape near the robot is estimated.
2. The desired posture (roll and pitch angles) of the body is then calculated on the basis of the estimated terrain shape.
 3. The desired positions of the subtracks that realize the desired posture of the robot body are also determined.
 4. Next, the stability of the desired posture and sub-track positions is evaluated.
 5. If the desired pose (posture of the robot body and subtrack positions) are unstable, then the desired pose is redefined and steps (3)–(5) are repeated.
 6. When the desired subtrack positions that realize a stable posture are generated, position control of the subtracks is finally performed.

In the following sections, we explain each step of the algorithm.

50.6.1 Ground Detection and Trimming of the Scanned Data

In this step, we obtain the scanned points U_{target} near the robot using the LIDAR sensors attached to the robot; ground detection is performed according to the approach described in the paper [50.59]. We first obtain two-dimensional terrain slices from three LIDAR sensors and integrate them according to each tagged and estimated position of the robot to generate the three-dimensional information of the terrain shape. At the end of this step, we filter distant points from the integrated terrain shape.

$$U_{\text{target}} = \{u_1, u_2, \dots, u_m\} \quad (50.22)$$

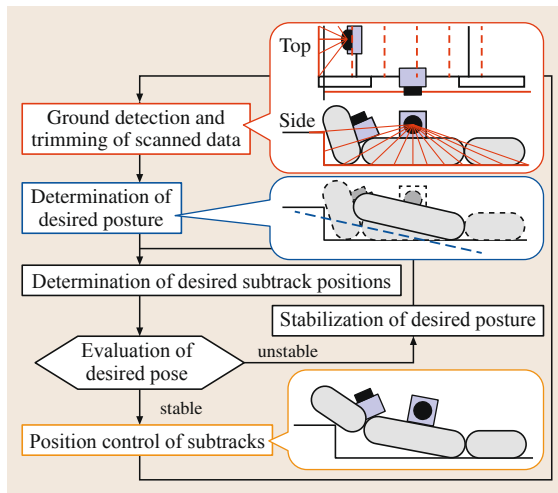

Fig. 50.19 Algorithm for autonomous control of subtracks

50.6.2 Determination of Desired Posture

We then determine the desired posture on the basis of the least-squares plane for the target terrain U_{target} . This is intended to enable smooth locomotion on rough terrain. Parameters a , b , and c of the least-squares plane $z = ax + by + c$ are determined using the following equations (an over-bar indicates the average of m scanned points in U_{target})

$$a = \frac{\alpha_{z,x}\alpha_{y,y} - \alpha_{x,y}\alpha_{y,z}}{\alpha_{x,x}\alpha_{y,y} - \alpha_{x,y}\alpha_{x,y}}, \quad (50.23)$$

$$b = \frac{\alpha_{y,z}\alpha_{x,x} - \alpha_{x,y}\alpha_{z,x}}{\alpha_{x,x}\alpha_{y,y} - \alpha_{x,y}\alpha_{x,y}}, \quad (50.24)$$

$$c = \bar{z}_v - \bar{x}_v a - \bar{y}_v b, \quad (50.25)$$

$$\alpha_{x,y} = \bar{x}_u \cdot \bar{y}_u - \bar{x}_u \cdot \bar{y}_u, \quad (50.26)$$

$$\alpha_{y,z} = \bar{y}_u \cdot \bar{z}_u - \bar{y}_u \cdot \bar{z}_u, \quad (50.27)$$

$$\alpha_{z,x} = \bar{z}_u \cdot \bar{x}_u - \bar{z}_u \cdot \bar{x}_u, \quad (50.28)$$

$$\alpha_{x,x} = \bar{x}_u \cdot \bar{x}_u - \bar{x}_u \cdot \bar{x}_u, \quad (50.29)$$

$$\alpha_{y,y} = \bar{y}_u \cdot \bar{y}_u - \bar{y}_u \cdot \bar{y}_u. \quad (50.30)$$

Then, a translation to the coordinate system, if the robot body is parallel to the least-squares plane of the ground surface and makes contact with the ground, is described by the following equation in quaternion algebra:

$$\begin{pmatrix} 0 \\ x'_{u'_i} \\ y'_{u'_i} \\ z'_{u'_i} \end{pmatrix} = q' \times \begin{pmatrix} 0 \\ x_{u_i} \\ y_{u_i} \\ z_{u_i} \end{pmatrix} \times q'^{-1} - \begin{pmatrix} 0 \\ 0 \\ 0 \\ \max(z_{u'_i}) \end{pmatrix}, \quad (50.31)$$

$$q' = \begin{pmatrix} \cos \frac{\theta_{\text{rot}}}{2} \\ b \sin \frac{\theta_{\text{rot}}}{2} \\ -a \sin \frac{\theta_{\text{rot}}}{2} \\ 0 \end{pmatrix}, \quad (50.32)$$

$$\theta_{\text{rot}} = \cos^{-1} \frac{1}{\sqrt{a^2 + b^2 + 1}}. \quad (50.33)$$

50.6.3 Determination of Desired Subtrack Positions

In this step, using the desired body posture and the integrated terrain slices, we determine the desired subtrack positions on the basis of the geometric model of contacts between the vehicle and the terrain surface.

Our application allows the operator to manually switch between the spreading and the folding control modes. Each control mode employs a corresponding geometric calculation method described in Sect. 50.4. In other words, the autonomous controller uses the corresponding calculation to determine the desired subtrack positions according to the control mode specified by the operator.

In both modes, we determine the desired subtrack positions to make contact with the ground through the desired robot posture. In particular, we calculate the angular position of each subtrack that makes contact with each point scanned by the left and the right LIDAR sensors. The desired position of each subtrack is determined for the maximum or minimum angular position of the subtrack in the spreading or folding mode, respectively.

50.6.4 Stability Evaluation of Desired Pose

In the proposed controller, we have adopted the normalized energy stability margin (NESM) [50.19] as the stability criterion for the desired pose. The stability of a desired pose is evaluated by NESM, and the pose is redefined if the stability is insufficient.

In the case of a tracked vehicle with four subtracks, four contact points (front-right, front-left, rear-right, and rear-left) can be determined by the step described in Sect. 50.6.3. In addition, the four axes of tumbling that pass through the front, rear, right, and left contact points can be assumed. Hence, the stability of a tracked

vehicle with four subtracks can be determined from the minimum value of the NESM about these four axes.

50.6.5 Stabilization of Desired Pose

When the NESM of the robot is less than a predetermined threshold, we repeat the following steps until a desired, stable pose is realized. This step is intended to realize the strategy 4:

- 1a. If the NESM about the front or rear is adopted, reduce the pitch angle of the desired posture to zero.
- 1b. When the NESM about the right or left is adopted, reduce the roll angle of the desired posture to zero.
2. Redefine the desired subtrack positions by recalculating them to realize the redefined desired posture.
3. Evaluate the NESM about the redefined posture and positions of subtracks.

50.6.6 Position Control of Subtracks

Finally, we perform position control of the subtracks to realize the desired subtrack position produced through the above-mentioned steps on the basis of the strategy described in the previous subsection.

All subtracks of Kenaf and Quince are controlled by microprocessors present on the built-in motor drivers. Each desired subtrack position is sent to the corresponding microprocessor as a reference for position control using the conventional proportional–integral–derivative (PID) controller.

50.7 Summary

In this chapter, an overview of the modeling and control of robots on the rough terrain motion has been provided. The target environment was rough terrains, which includes a variety of ground conditions. In the case of weak and fine gravel, the motion of a wheeled mobile robot becomes relatively complicated because the interaction mechanics of the wheel in rough terrains differs greatly from that of an indoor robot on a flat surface. In this chapter, we introduced a terramechanics-

based model for the interactions between wheels and deformable terrains. Furthermore, we explained the steering control of wheeled mobile robots to enable path-following in such environments. In the case of an environment with heaps of rubble, the approach for controlling robots is different from the terramechanics approach. Therefore, we introduced an initial attempt at a sensor-based approach that involved measuring the terrain shape.

51. Modeling and Control of Underwater Robots

Gianluca Antonelli, Thor I. Fossen, Dana R. Yoerger

This chapter deals with modeling and control of underwater robots. First, a brief introduction showing the constantly expanding role of marine robotics in oceanic engineering is given; this section also contains some historical backgrounds. Most of the following sections strongly overlap with the corresponding chapters presented in this handbook; hence, to avoid useless repetitions, only those aspects peculiar to the underwater environment are discussed, assuming that the reader is already familiar with concepts such as fault detection systems when discussing the corresponding underwater implementation. The modeling section is presented by focusing on a coefficient-based approach capturing the most relevant underwater dynamic effects. Two sections dealing with the description of the sensor and the actuating systems are then given. Autonomous underwater vehicles require the implementation of mission control system as well as guidance and control algorithms. Underwater localization is also discussed. Underwater manipulation is then briefly approached. Fault detection and fault tolerance, together with the coordination control of multiple underwater vehicles, conclude the theoretical part of the

chapter. Two final sections, reporting some successful applications and discussing future perspectives, conclude the chapter. The reader is referred to Chap. 25 for the design issues.

The world's oceans cover 2/3 of the Earth's surface and have been critical to human welfare throughout history. As in ancient times, they enable the transport of goods between nations. Presently, the seas represent critical sources of food and other resources such as oil and gas.

In the near term, we may soon see the emergence of offshore mining for metals as well as the exploitation of gas hydrates. Conversely, the ocean can also threaten human safety and damage infrastructure through natural phenomena such as hurricanes and tsunamis.

51.1 The Expanding Role of Marine Robotics in Oceanic Engineering

Our scientific understanding of the deep sea is expanding rapidly through the use of a variety of technologies.

The first scientific explorations were conducted primarily through the use of diving and human-occupied

submersibles, complemented by a variety of other technologies such as towed or lowered instruments, trawls, dredges, autonomous seafloor instruments, and deep-sea drilling. More recently remotely operated and autonomous vehicles have begun to revolutionize seafloor exploration, often returning superior data at reduced costs. In the near future, seafloor observatories linked by fiber-optic cables and satellites will return massive amounts of data from coastal and deep-sea sites. These observations will complement those from conventional expeditionary investigations, and will require teleoperated or robotic intervention during installation and for service. An example of a remotely operated vehicle developed for the scientific study of the seafloor is the Jason 2 vehicle developed at the Woods Hole Oceanographic Institution (shown in Fig. 51.1), and a list of remotely operated vehicles for scientific exploration appears in Table 51.1 (the last vehicle in the table, Kaiko, was lost several years ago).

Offshore oil and gas installations are presently serviced almost exclusively by remotely operated vehicles (ROVs), physically connected via a tether to receive power and data, with human divers used only for the shallowest installations. Subsea systems require extensive work capability during installation, and need frequent inspection and intervention to support drilling operations, actuate valves, repair or replace subsea components, and to accomplish a variety of tasks required to maintain production rates and product quality. The trend toward robotic and teleoperated subsea intervention is certain to continue as offshore oil and gas production moves into deeper waters, and economic considerations push key production steps from surface platforms to the seafloor. Remotely operated manipulators enable these systems to perform complex tasks such as debris removal, cleaning using abrasive tools,

and to operate a variety of nondestructive testing tools. The effectiveness of using ROVs decreases with depth mainly due to the cost increase and the difficulties of handling the long tether.

Autonomous underwater vehicles (AUVs) are free-swimming unoccupied underwater vehicles that can overcome the limitations imposed by ROV tethers for some tasks. Such vehicles carry their own energy supplies (presently batteries, perhaps fuel cells in the future) and communicate only through acoustics and perhaps optical links in the near future. Limited communications require these vehicles to operate independently of continuous human control, in many cases the vehicles operate completely autonomously. AUVs are currently used for scientific survey tasks, oceanographic sampling, underwater archeology and under-ice survey. Military applications, such as mine detection and landing site survey, are presently operational, and more ambitious applications such as long-term undersea surveillance are in engineering development. Presently, AUVs are incapable of sampling or manipulations tasks like those done routinely by ROVs, as typical work environments tend to be complex and challenging even to skilled human pilots.

Today, approximately 1000 AUVs are operational, many of them experimental. However, they are maturing rapidly. Recently several companies now offer commercial services with AUVs. As an example, for the oil and gas industry the cost reduction of a survey performed with an AUVs instead of a towed vehicle is up to 30% and the data quality is generally higher. Likewise, commercial manufacturers in several countries now offer turnkey AUV systems for specific, well-defined tasks. Currently, remotely operated manip-

ulators are standard equipment for most ROVs, while on the contrary autonomous manipulation is still a research challenge; the projects SAUVIM [51.1], ALIVE [51.2] and TRIDENT [51.3] were devoted to studying this control problem.  VIDEO 88 shows a graphical rendering of a mission with the AUV Nereus,  VIDEO 87 shows the perspective view from the Remus AUV,  VIDEO 92 a 10-minutes long documentary of an underice mission and finally  VIDEO 90 a strong interaction with a shark.

51.1.1 Historical Background

Boats have been used by humans since the start of recorded history, but vehicles able to go under water are more recent. Perhaps the first recorded idea of an underwater machine came from Aristotle; according to legend he built the: *skaphe andros* (boat-man) that allowed Alexander the Great (Alexander III of Macedonia, 356–323 BC) to stay submerged for at least half a day during the war of Tiro in 325 BC. This is probably unrealistic; if true it would precede Archimedes' law, which was first articulated in approximately 250 BC. Leonardo Da Vinci may have been the first to design an underwater vehicle. His efforts

were recorded in the *Codice Atlantico* (*Codex Atlanticus*), written between 1480 and 1518. Legends say that Leonardo worked on the idea of an underwater military machine but he destroyed the results as he judged them to be too dangerous. The first use of feedback theory for marine control was probably the Northseeking device, patented in 1908, that used gyroscopic principals to develop the first autopilot [51.4]. From that point on, the use of feedback theory in marine control grew continuously; it is interesting to notice that the proportional–integral–derivative (PID) control commonly used today in numerous industrial applications was first formally analyzed in 1929 by Minorsky [51.5]. The first remotely operated underwater vehicle, POODLE, was built in 1953, and the ROV evolved through the 1960s and 1970s, mostly for military purposes. In the 1980s ROVs became established for use in the commercial offshore industry and began to emerge for scientific applications. The first tetherless, autonomous vehicles were built for experimental purposes in the 1970s. Currently, AUVs are becoming increasingly commonplace for scientific, military, and commercial applications. Turnkey AUV systems for a range of tasks are available from commercial vendors, and AUV services can be acquired from a number of companies [51.6].

51.2 Underwater Robotics

51.2.1 Modeling

A rigid body is completely described by its position and orientation with respect to a reference frame $\Sigma_i, O_i - xyz$ that is supposed to be Earth-fixed and inertial. Let us define $\eta_1 \in \mathbb{R}^3$ as

$$\eta_1 = (x \ y \ z)^T,$$

the vector of the body position coordinates in an Earth-fixed reference frame. The vector $\dot{\eta}_1$ is the corresponding time derivative (expressed in the Earth-fixed frame). If one defines

$$v_1 = (u \ v \ w)^T$$

as the linear velocity of the origin of the body-fixed frame $\Sigma_b, O_b - x_b \ y_b \ z_b$ with respect to the origin of the Earth-fixed frame expressed in the body-fixed frame (from now on: body-fixed linear velocity) the following relation between the defined linear velocities holds

$$v_1 = R_1^B \dot{\eta}_1, \quad (51.1)$$

where R_1^B is the rotation matrix expressing the transformation from the inertial frame to the body-fixed frame.

Let us define $\eta_2 \in \text{SO}(3)$ as

$$\eta_2 = (\phi \ \theta \ \psi)^T$$

the vector of body Euler angle coordinates in a Earth-fixed reference frame. In the nautical field those are commonly named roll, pitch, and yaw. Yaw is defined as rotation around the z axis of the fixed frame; pitch is defined as rotation around the y axis resulting after the yaw movement; and roll is defined as rotation around the x axis resulting after both yaw and pitch movements. The vector $\dot{\eta}_2$ is the corresponding time derivative (expressed in the inertial frame). Let us define

$$v_2 = (p \ q \ r)^T$$

as the angular velocity of the body-fixed frame with respect to the Earth-fixed frame expressed in the body-fixed frame (from now on: body-fixed angular velocity). The vector $\dot{\eta}_2$ does not have a physical interpretation and it is related to the body-fixed angular velocity by a proper Jacobian matrix

$$v_2 = J_{k,o}(\eta_2) \dot{\eta}_2. \quad (51.2)$$

The matrix $\mathbf{J}_{k,o} \in \mathbb{R}^{3 \times 3}$ can be expressed in terms of the Euler angles as

$$\mathbf{J}_{k,o}(\eta_2) = \begin{pmatrix} 1 & 0 & -s_\theta \\ 0 & c_\phi & c_\theta s_\phi \\ 0 & -s_\phi & c_\theta c_\phi \end{pmatrix}, \quad (51.3)$$

where c_α and s_α are abbreviations for $\cos(\alpha)$ and $\sin(\alpha)$, respectively. The matrix $\mathbf{J}_{k,o}(\eta_2)$ is not invertible for every value of η_2 . In detail, it is

$$\mathbf{J}_{k,o}^{-1}(\eta_2) = \frac{1}{c_\theta} \begin{pmatrix} 1 & s_\phi s_\theta & c_\phi s_\theta \\ 0 & c_\phi c_\theta & -c_\theta s_\phi \\ 0 & s_\phi & c_\phi \end{pmatrix}, \quad (51.4)$$

that it is singular for $\theta = (2l+1)\frac{\pi}{2}$ rad, with $l \in \mathbb{N}$, i. e., for a pitch angle of $\pm\frac{\pi}{2}$ rad.

The rotation matrix \mathbf{R}_I^B , needed in (51.1) to transform the linear velocities, is expressed in terms of the Euler angles by

$$\mathbf{R}_I^B(\eta_2) = \begin{pmatrix} c_\psi c_\phi & s_\psi c_\phi & -s_\theta \\ -s_\psi c_\phi + c_\psi s_\theta s_\phi & c_\psi c_\phi + s_\psi s_\theta s_\phi & s_\phi c_\theta \\ s_\psi s_\phi + c_\psi s_\theta c_\phi & -c_\psi s_\phi + s_\psi s_\theta c_\phi & c_\phi c_\theta \end{pmatrix}. \quad (51.5)$$

Table 51.2 shows the common notation used for marine vehicles according to the Society of Naval Architects and Marine Engineers (SNAMEs) notation [51.7]; a sketch is shown in Fig. 51.2.

As for any representation of a rigid body's orientation several possibilities arise, among them, the use of a four-parameter description given by unit quaternions. The term *quaternion* was introduced by Hamilton in

Table 51.2 Common notation for the motion of a marine vehicle

		Forces and moments	$\mathbf{v}_1, \mathbf{v}_2$	η_1, η_2
Motion in the x -direction	Surge	X	u	x
Motion in the y -direction	Sway	Y	v	y
Motion in the z -direction	Heave	Z	w	z
Rotation about the x -axis	Roll	K	p	ϕ
Rotation about the y -axis	Pitch	M	q	θ
Rotation about the z -axis	Yaw	N	r	ψ

Fig. 51.2 Motion variables for an underwater vehicle

1840, 70 years after the introduction of a four-parameter rigid-body attitude representation by Euler. An introduction to alternative orientation representations can be found in Chap. 2 and concerning the marine environment in [51.8].

It is useful to collect the kinematic equations in six-dimensional matrix forms. Let us define the vector $\eta \in \mathbb{R}^6$ as

$$\eta = \begin{pmatrix} \eta_1 \\ \eta_2 \end{pmatrix}, \quad (51.6)$$

and the vector $\mathbf{v} \in \mathbb{R}^6$ as

$$\mathbf{v} = \begin{pmatrix} v_1 \\ v_2 \end{pmatrix}, \quad (51.7)$$

and, defining the matrix $\mathbf{J}_e(\mathbf{R}_I^B) \in \mathbb{R}^{6 \times 6}$

$$\mathbf{J}_e(\mathbf{R}_I^B) = \begin{pmatrix} \mathbf{R}_I^B & \mathbf{0}_{3 \times 3} \\ \mathbf{0}_{3 \times 3} & \mathbf{J}_{k,o} \end{pmatrix}, \quad (51.8)$$

where the rotation matrix \mathbf{R}_I^B is given in (51.5) and $\mathbf{J}_{k,o}$ is given in (51.3),

$$\mathbf{v} = \mathbf{J}_e(\mathbf{R}_I^B) \dot{\eta}. \quad (51.9)$$

The inverse mapping, given the block-diagonal structure of \mathbf{J}_e , is given by

$$\dot{\eta} = \mathbf{J}_e^{-1}(\mathbf{R}_I^B) \mathbf{v} = \begin{pmatrix} \mathbf{R}_I^B & \mathbf{0}_{3 \times 3} \\ \mathbf{0}_{3 \times 3} & \mathbf{J}_{k,o}^{-1} \end{pmatrix} \mathbf{v}, \quad (51.10)$$

where $\mathbf{J}_{k,o}^{-1}$ is given in (51.4).

Defining as

$$\boldsymbol{\tau}_v = \begin{pmatrix} \tau_1 \\ \tau_2 \end{pmatrix},$$

the vector of generalized forces, where

$$\boldsymbol{\tau}_1 = (X \ Y \ Z)^T, \quad (51.11)$$

the resultant forces acting on the rigid body expressed in a body-fixed frame, and

$$\tau_2 = (K \ M \ N)^T, \quad (51.12)$$

the corresponding resultant moment to the pole O_b , it is possible to rewrite the Newton–Euler equations of motion of a rigid body moving in the space as

$$\mathbf{M}_{RB} \dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v})\mathbf{v} = \tau_v. \quad (51.13)$$

The derivation of (51.13) can be found in Chap. 3.

The matrix \mathbf{M}_{RB} is constant, symmetric, and positive definite, i. e., $\mathbf{M}_{RB} = \mathbf{0}$ and $\mathbf{M}_{RB} = \mathbf{M}_{RB}^T > \mathbf{0}$. Its unique parametrization is of the form

$$\mathbf{M}_{RB} = \begin{pmatrix} m\mathbf{I}_3 & -m\mathbf{S}(\mathbf{r}_C^b) \\ m\mathbf{S}(\mathbf{r}_C^b) & \mathbf{I}_{O_b} \end{pmatrix}, \quad (51.14)$$

where \mathbf{r}_C^b is the 3×1 distance vector to the center of gravity (CG) expressed in the body-fixed frame, \mathbf{I}_3 is the 3×3 identity matrix, and \mathbf{I}_{O_b} is the inertia tensor expressed in the body-fixed frame $\mathbf{S}(\mathbf{x})$ is the matrix operator performing the cross product between two (3×1) vectors

$$\mathbf{S}(\mathbf{x}) = \begin{pmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{pmatrix}.$$

On the other hand, there does not exist a unique parametrization of the matrix \mathbf{C}_{RB} , which represents the Coriolis and centripetal terms. It can be demonstrated that the matrix \mathbf{C}_{RB} can always be parameterized such that it is skew symmetric, i. e.,

$$\mathbf{C}_{RB}(\mathbf{v}) = -\mathbf{C}_{RB}^T(\mathbf{v}) \quad \forall \mathbf{v} \in \mathbb{R}^6; \quad (51.15)$$

explicit expressions for \mathbf{C}_{RB} can be found in [51.8].

Notice that (51.13) can be greatly simplified if the origin of the body-fixed frame is chosen to be coincident with the central frame, i. e., $\mathbf{r}_C^b = \mathbf{0}$.

Hydrodynamic Generalized Forces

Equation (51.13) represents the motion of a rigid body in an empty space, while dealing with ships or underwater vehicles requires the consideration of the presence of the hydrodynamics generalized forces, i. e., the forces and moments caused by the presence of the fluid. In hydrodynamics it is common to assume that the generalized hydrodynamics forces on a rigid body can be linearly superimposed [51.9]; in particular, those are separated into radiation-induced forces, environmental disturbances, and restoring forces due to gravity and buoyancy.

Radiation-induced forces are defined as the:

forces on the body when the body is forced to oscillate with the wave excitation frequency and there are no incident waves;

these can be identified as the sum of the *added mass* due to the inertia of the surrounding fluid and the *radiation-induced potential damping* due to the energy dissipated by generated surface waves.

Environmental disturbances can be identified as the generalized forces caused by the wind, the waves, and the ocean current.

The overall equations of motions can therefore be written in matrix form as [51.8, 10, 11]

$$\mathbf{M}_v \dot{\mathbf{v}} + \mathbf{C}_v(\mathbf{v})\mathbf{v} + \mathbf{D}_v(\mathbf{v})\mathbf{v} + \mathbf{g}_v(\mathbf{R}_B^I) = \tau_v, \quad (51.16)$$

where $\mathbf{M}_v = \mathbf{M}_{RB} + \mathbf{M}_A$ and $\mathbf{C}_v = \mathbf{C}_{RB} + \mathbf{C}_A$ also include the added mass terms.

In the following sections these generalized forces, specific to the marine environment, will be briefly discussed.

Added Mass and Inertia

When a rigid body is moving in a fluid, the additional inertia of the fluid surrounding the body that is accelerated by the movement of the body has to be considered. This effect can be neglected in industrial robotics since the density of the air is much lower than the density of a moving mechanical system. In underwater applications, however, the density of the water, $\rho \approx 1000 \text{ kg/m}^3$, is comparable with the density of the vehicles. In particular, at 0°C , the density of freshwater is 1002.68 kg/m^3 ; for sea water with 3.5% salinity it is $\rho = 1028.48 \text{ kg/m}^3$.

The fluid surrounding the body is accelerated with the body, so a force is necessary to achieve this acceleration, while the fluid exerts a reaction force which is equal in magnitude and opposite in direction. This reaction force is the added mass contribution. The added mass is not a quantity of fluid to add to the system such that it has an increased mass. Different properties hold with respect to the 6×6 inertia matrix of a rigid body due to the fact that the added mass is a function of the body's surface geometry.

The hydrodynamic force along \mathbf{x}_b due to the linear acceleration in the \mathbf{x}_b -direction is defined as

$$X_A := -X_{ii}\dot{u}, \quad \text{where} \quad X_{ii} := X_{ii} = \frac{\partial X}{\partial \dot{u}},$$

where the symbol ∂ denotes the partial derivative. In the same way it is possible to define all the remaining 35 elements that relate the six force/moment components $(X \ Y \ Z \ K \ M \ N)^T$ to the six linear/angular accelerations $(\dot{u} \ \dot{v} \ \dot{w} \ \dot{p} \ \dot{q} \ \dot{r})^T$. These elements can be grouped

into the added mass matrix $\mathbf{M}_A \in \mathbb{R}^{6 \times 6}$. Usually, all the elements of the matrix are nonzero.

In general, added mass and potential damping will be frequency dependent and depend on the forward speed. This is also the case for certain viscous damping terms (skin friction, roll damping, etc.). This gives a pseudo differential equation describing the frequency response of the vehicle. Since some of the coefficients depend on the frequency this is not an ordinary differential equation (ODE). The frequency equation, however, can be transformed to the time domain using the concepts described in [51.12] and [51.13], and recently in [51.14]. The time-domain equations will in general include fluid memory effects [51.4]. However, underwater robots are usually modelled using maneuvering theory where the potential coefficients are evaluated at the zero frequency. The resulting equation is an ODE where the added inertia matrix \mathbf{M}_A is constant, speed independent, and positive definite

$$\mathbf{M}_A = \mathbf{M}_A^T > \mathbf{0}, \quad \dot{\mathbf{M}}_A = \mathbf{0}. \quad (51.17)$$

This result is well known from ship hydrodynamics; [51.15] for instance. The matrix \mathbf{M}_A can be computed using numerical programs such as WAMIT or Matlab, based on the US Air Force Digital Datcom [51.16]; in this case, the zero-frequency result should be used, that is, $\mathbf{M}_A = \mathbf{A}(0)$ where $\mathbf{A}(\omega)$ is the frequency-dependent added mass matrix. The potential damping matrix will be small compared to the viscous effects and drag/lift terms. Hence, this term can be set to zero for underwater vehicles. If the added mass is computed experimentally, it is common practice to symmetrize the results such that

$$\mathbf{M}_A = \frac{1}{2} (\mathbf{A}_{\text{exp}} + \mathbf{A}_{\text{exp}}^T),$$

where \mathbf{A}_{exp} denotes the experimentally obtained added mass terms.

If the body is completely submerged in the water and is designed with port/starboard symmetry (xz -plane) as is common for underwater vehicles in six degrees-of-freedom (DOF), the following structure of the matrices \mathbf{M}_A can be considered

$$\mathbf{M}_A = - \begin{pmatrix} X_{\dot{u}} & 0 & X_{\dot{w}} & 0 & X_{\dot{q}} & 0 \\ 0 & Y_{\dot{v}} & 0 & Y_{\dot{p}} & 0 & Y_{\dot{r}} \\ Z_{\dot{u}} & 0 & Z_{\dot{w}} & 0 & Z_{\dot{q}} & 0 \\ 0 & K_{\dot{v}} & 0 & K_{\dot{p}} & 0 & K_{\dot{r}} \\ M_{\dot{u}} & 0 & M_{\dot{w}} & 0 & M_{\dot{q}} & 0 \\ 0 & N_{\dot{v}} & 0 & N_{\dot{p}} & 0 & N_{\dot{r}} \end{pmatrix}. \quad (51.18)$$

The added mass coefficients can theoretically be derived by exploiting the geometry of the rigid body or numerically by strip theory [51.17].

In [51.18] the coefficients for the experimental AUV Phoenix of the Naval Postgraduate School (NPS) are reported. These coefficients have been derived experimentally, and the geometry gives a nondiagonal \mathbf{M}_A matrix. To provide an order of magnitude for the added mass terms, for the vehicle mass of about 5000 kg, the $X_{\dot{u}}$ is approximately -500 kg.

The added mass also makes an *added* Coriolis and centripetal contribution. It can be demonstrated that the matrix expression can always be parameterized such that

$$\mathbf{C}_A(\mathbf{v}) = -\mathbf{C}_A^T(\mathbf{v}), \quad \forall \mathbf{v} \in \mathbb{R}^6,$$

whose symbolic expressions can be found in [51.4].

Hydrodynamic Damping

The hydrodynamic damping for marine vehicles is mainly caused by:

- Potential damping
- Skin friction
- Wave drift damping
- Vortex shedding damping
- Viscous damping.

The radiation-induced potential damping due to forced body oscillations is commonly known as potential damping; its dynamic contribution is usually negligible with respect to, e.g., the viscous friction for underwater vehicles while it may be significant for surface vessels.

Linear skin friction is due to laminar boundary layers and can affect the low-frequency motion of the vehicle. Together with this effect, at high frequencies it is possible to observe a quadratic, or nonlinear, skin friction phenomenon caused by turbulent boundary layers.

Wave drift damping is the dominant dynamic damping effect in surge motion of surface vessels in high sea. It can be considered as an added resistance for boats advancing in waves; its drift is proportional to the square of the significant wave height. In the sway and yaw directions, however, its dynamic contribution is negligible with respect to the effect of vortex shedding.

A body moving in a fluid causes a separation of the flow; this can still be considered as laminar in the upstream while two antisymmetric vortices can be observed in the downstream. In case that the body is a cylinder moving in a direction normal to its axis, the result is a periodic force normal to both the velocity and the axis. This effect may cause the oscillation of cables and other underwater structures. However, concerning underwater vehicles, this effect is negligible for

ROVs and may be counteracted by designing proper small control surfaces for torpedo-like AUVs.

Vortex shedding is an unsteady flow that takes place at special flow velocities (according to the size and shape of the cylindrical body). In this flow vortices are created at the back of the body, periodically from each side.

The viscosity of the fluid also causes dissipative forces. These are composed of drag and lift forces, the former being parallel to the relative velocity of the vehicle with respect to the water while the latter are normal to it. For a sphere moving in a fluid, the drag force can be modeled as [51.9]

$$F_{\text{drag}} = \frac{1}{2} \rho U^2 S C_d(R_n), \quad (51.19)$$

where ρ is the fluid density, U is the velocity of the sphere, S is the frontal area of the sphere, C_d is the nondimensional drag coefficient, and R_n is the Reynolds number. For a generic body, S is the projection of the frontal area along the flow direction. The drag force can be considered as the sum of two physical effects: the frictional contribution of the surface whose normal is perpendicular to the flow velocity, and the pressure contribution of the surface whose normal is parallel to the flow velocity. For a hydrofoil moving in a fluid, the lift force can be modeled as [51.9]

$$F_{\text{lift}} = \frac{1}{2} \rho U^2 S C_l(R_n, \alpha), \quad (51.20)$$

where S is now the area, C_l is the nondimensional lift coefficient, and α is the angle of attack, i.e., the angle between the relative velocity and the tangent to the surface. For small angles of attack, i.e., $|\alpha| < 10^\circ$, the lift coefficient is approximatively proportional to α and rapidly decays to zero as α increases [51.19].

The drag and lift coefficients are therefore dependent on the Reynolds number, i.e., on the laminar/turbulent fluid motion

$$R_n = \frac{\rho |U| D}{\mu},$$

where D is the characteristic dimension of the body perpendicular to the direction of U and μ is the dynamic viscosity of the fluid. Table 51.3 reports the drag coefficients as a function of the Reynolds number for a cylinder [51.20].

Table 51.3 Lift and drag coefficient for a cylinder

Reynolds number	Regime motion	C_d	C_l
$R_n < 2 \times 10^5$	Subcritical flow	1	3–0.6
$2 \times 10^5 < R_n < 5 \times 10^5$	Critical flow	1–0.4	0.6
$5 \times 10^5 < R_n < 3 \times 10^6$	Transcritical flow	0.4	0.6

A common simplification considers only linear and quadratic damping terms and group these into a matrix \mathbf{D}_v as in (51.16) such that

$$\mathbf{D}_v(\mathbf{v}) > \mathbf{0}, \quad \forall \mathbf{v} \in \mathbb{R}^6.$$

Gravity and Buoyancy

When a rigid body is completely or partially submerged in a fluid under the effect of the gravity two more forces have to be considered: the gravitational force and buoyancy. The latter is the only hydrostatic effect, i.e., it is not a function of the relative movement between the body and fluid.

Let us define as

$$\mathbf{g}^I = (0 \ 0 \ 9.81)^T \text{m/s}^2$$

the acceleration of gravity. This effect is not constant but varies with depth, longitude, and latitude; however, this value is usually accurate enough for most applications except for inertial navigation systems.

For a completely submerged body the computation of these dynamic effects is straightforward. The submerged weight of the body is defined as $W = m \|\mathbf{g}^I\|$, while its buoyancy $B = \rho \nabla \|\mathbf{g}^I\|$, where ∇ is the volume of the body and m is its mass. The gravity force, which acts at the center of mass \mathbf{r}_C^B , is represented in the body-fixed frame by

$$\mathbf{f}_G(\mathbf{R}_I^B) = \mathbf{R}_I^B \begin{pmatrix} 0 \\ 0 \\ W \end{pmatrix},$$

while the buoyancy force, acting at the center of buoyancy \mathbf{r}_B^B , is represented in the body-fixed frame by

$$\mathbf{f}_B(\mathbf{R}_I^B) = -\mathbf{R}_I^B \begin{pmatrix} 0 \\ 0 \\ B \end{pmatrix}.$$

The 6×1 vector of force/moment due to gravity and buoyancy in the body-fixed frame, included in the left-hand side of the equations of motion, is represented by

$$\mathbf{g}_v(\mathbf{R}_I^B) = - \begin{pmatrix} \mathbf{f}_G(\mathbf{R}_I^B) + \mathbf{f}_B(\mathbf{R}_I^B) \\ \mathbf{r}_G^B \times \mathbf{f}_G(\mathbf{R}_I^B) + \mathbf{r}_B^B \times \mathbf{f}_B(\mathbf{R}_I^B) \end{pmatrix}.$$

In the following, the symbol $\mathbf{r}_G^B = (x_G \ y_G \ z_G)^T$ (with $\mathbf{r}_G^B = \mathbf{r}_C^B$) will be used for the center of gravity. The expression for \mathbf{g}_v in terms of the Euler angles is

$$\mathbf{g}_v(\eta_2) = \begin{pmatrix} (W-B)s_\theta \\ -(W-B)c_\theta s_\phi \\ -(W-B)c_\theta c_\phi \\ -(y_G W - y_B B)c_\theta c_\phi + (z_G W - z_B B)c_\theta s_\phi \\ (z_G W - z_B B)s_\theta + (x_G W - x_B B)c_\theta c_\phi \\ -(x_G W - x_B B)c_\theta s_\phi - (y_G W - y_B B)s_\theta \end{pmatrix}. \quad (51.21)$$

Current

Ocean currents are mainly caused by tidal movement, the atmospheric wind system over the sea surface, heat exchange at the sea surface, salinity changes, the Coriolis force due to the Earth's rotation, nonlinear waves, the major ocean circulations such as the Gulf Stream, the effect of setup phenomena or storm surges, and strong density gradients in the upper ocean. Currents can be very different due to local climatic and/or geographic characteristics; as an example, in fjords, the tidal effect can cause currents of up to 3 m/s, moreover, specific mathematical models exist for the various components [51.8].

Let us assume that the ocean current, expressed in the inertial frame, \mathbf{v}_c^I , is constant and irrotational, i. e.,

$$\mathbf{v}_c^I = (v_{c,x} \ v_{c,y} \ v_{c,z} \ 0 \ 0 \ 0)^T,$$

and $\dot{\mathbf{v}}_c^I = \mathbf{0}$; its effects can be added to the dynamics of a rigid body moving in a fluid simply by considering the relative velocity in the body-fixed frame

$$\mathbf{v}_r = \mathbf{v} - \mathbf{R}_I^B \mathbf{v}_c^I \quad (51.22)$$

in the derivation of the added Coriolis and centripetal and the damping terms.

$$\mathbf{M}_v \dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v})\mathbf{v} + \mathbf{C}_A(\mathbf{v}_r)\mathbf{v}_r + \mathbf{D}_v(\mathbf{v}_r)\mathbf{v}_r + \mathbf{g}_v(\mathbf{R}_I^B) = \boldsymbol{\tau}_v. \quad (51.23)$$

Notice that the term $\mathbf{C}_A(\mathbf{v}_r)\mathbf{v}_r$ includes the important destabilizing effect known as the Munk moment [51.9].

If $\mathbf{D}_v(\mathbf{v}_r)$ is unknown, quadratic surge resistance and the cross-flow drag principle can be used to describe the dissipative forces and moments in surge, sway, and yaw [51.9]. Moreover

$$\mathbf{C}_A(\mathbf{v}_r)\mathbf{v}_r + \mathbf{D}_v(\mathbf{v}_r)\mathbf{v}_r \approx (X_c \ Y_c \ 0 \ 0 \ 0 \ N_c)^T \quad (51.24)$$

for large relative current angles $|\beta_c - \psi|$, where β_c is the current direction, the cross-flow principles models

the sway force Y_c and yaw moment N_c as

$$Y_c = \frac{\rho}{2} \int_L H(x) C_D(x) v_r^x(x) |v_r^x(x)| dx \quad (51.25)$$

$$N_c = \frac{\rho}{2} \int_L x H(x) C_D(x) v_r^x(x) |v_r^x(x)| dx - X_{r|r} r |r|, \quad (51.26)$$

where L is the vehicle length, $H(x)$ is the vehicle height, $C_D(x)$ is the two-dimensional drag coefficient, and $v_r^x(x) = v_r + rx$ is the relative cross-flow velocity at x . In practice $C_D(x)$ can be chosen as a constant between 0 and 1. The proper value can be determined by curve fitting of experimental data. Along the surge direction, however, the quadratic damping contribution X_c is still well represented by a term proportional to the square of the relative velocity, whose symbolic expression can be written as

$$X_c = -X_{u|u}|u_r|u_r|, \quad (51.27)$$

where $-X_{u|u}|u_r|u_r| > 0$ is the quadratic surge damping coefficient, which can be found by curve fitting of experimental data or relating it to the drag coefficient C_d as in (51.19). The approximation embedded in (51.24) does not represent sufficiently enough the dynamics at low velocities, when the quadratic terms are negligible. Hence, it is common to add a linear optional damper in surge, sway and yaw; this can be physically explained as skin friction which shows a linear behavior.

Alternatively, the computation of the quadratic surge resistance, nonlinear roll damping, and the cross-flow drag effect can be made by resorting to the Datcom database for aircraft, as shown in [51.21].

Model Properties

For completely submerged bodies in an ideal fluid moving at low velocity where there are no currents or waves, (51.16) satisfies the following properties:

- The inertia matrix is symmetric and positive definite, i. e.,

$$\mathbf{M}_v = \mathbf{M}_v^T > \mathbf{0}.$$

- The damping matrix is positive definite, i. e.,

$$\mathbf{D}_v(\mathbf{v}) > \mathbf{0}.$$

- The matrix $\mathbf{C}_v(\mathbf{v})$ is skew symmetric, i. e.,

$$\mathbf{C}_v(\mathbf{v}) = -\mathbf{C}_v^T(\mathbf{v}), \forall \mathbf{v} \in \mathbb{R}^6.$$

Hydrodynamic Modeling

The mathematical model of an underwater robot as expressed in (51.16) is of great importance; even when

Sensor model	Description
WHN300	300 kHz Acoustic Doppler Current Profiler/Doppler Velocity Log, manufactured by Teledyne/RD Instruments
8CB4000I	Paroscientific Digiquartz pressure sensor, 4000 m full scale
Gulpers	10 × 2 liter Water Samplers
HS2	Hobilabs 2 channel backscatter/fluorometer, 420 nm/700 nm excitation
LISST-100	Sequoia Scientific particle size spectrum instrument
ISUS	In-situ ultraviolet spectrometer for nitrate measurement
2xSBE3/SBE4	Seabird temperature/conductivity instrument, 2 pairs of instruments carried
SBE43	Seabird dissolved oxygen cell
2xSBE5	Pumps for C/T/DO/ISUS and C/T/LISST flow paths
UBAT	Wetlabs bioluminescence assessment tool (bathyphtometer for measuring plankton bio-luminescence)
LOPC	Laser Optical Plankton Counter
ECO-CDOM	Fluorometer for measuring CDOM (colored dissolved organic matter)

simplified it captures the most important part of the dynamics. Moreover, it is in a form appropriate for control design. A wide literature exists on AUV/ROV controllers whose stability relies on the properties reported above. On the other hand, there are working conditions in which these assumptions are no longer valid, i.e., when the AUV is traveling at high speed, or close to the surface, or when its shape does not allow geometric simplifications. The latter is the case of, e.g., several ROVs. In addition, it is still common to design the controllers for AUVs based on linearized models and to control ROVs with simple PID controllers.

These considerations justify a modeling effort to calculate the hydrodynamic terms more accurately with the aim of prediction, simulation, and performance analysis rather than control design. This can be done by switching from a coefficient-based approach, such as that presented above, to a component modeling method, the latter being based on computational fluid dynamics theory. In detail, each vehicle geometry, with its specific angle of attack and sideslip, is taken into consideration when computing the hydrodynamic forces/moments. This increased computational effort makes it possible to capture some dynamic effects, such as the vortex-induced roll moment, not justifiable with the coefficient-based approach.

The control plant model is usually a simplified model that captures the most important parts of the dynamics. The most accurate model of the vehicle should be used for prediction and motion simulation.

51.2.2 Sensor Systems

Underwater vehicles are equipped with a sensor system devoted to enabling motion control as well as accomplishing the specific mission it has been commanded to complete. In the latter case, sensors developed for chemical/biological measurements or mapping may be

installed, which is beyond the scope of this chapter. For seek of example, Table 51.4 reports the payload for the AUV Dorado, shown in Fig. 51.3.

AUVs need to operate underwater most of the time; one of the major problems with underwater robotics is in the localization task due to the absence of a single, proprioceptive sensor to measure the vehicle position. The global positioning system (GPS) cannot be used underwater. Redundant multisensor systems are commonly combined using state estimation or sensor fusion techniques to provide fault detection and tolerance capability to the vehicle. Table 51.5 lists the types of sensors and the corresponding variable measured commonly available for unmanned underwater vehicles (UUVs).

The sensors that can be found on an underwater vehicle are:

- **Compass:** A gyrocompass can provide an estimate of geodetic north accurate to a fraction of a degree. Magnetic compasses can provide estimates of

**Fig. 51.3** The AUV Dorado (courtesy of Monterey Bay Aquarium Research Institute [51.22])

Table 51.5 UUVs: possible instrumentation

Sensor	Measured variable
Inertial system	Linear acceleration and angular velocity
Pressure meter	Vehicle depth
Frontal sonar	Distance from obstacles
Vertical sonar	Distance from the bottom
Doppler velocity log	Relative velocity vehicle/bottom
Current meter	Relative velocity vehicle/current
Global positioning system	Absolute position at the surface
Compass	Orientation
Acoustic positioning	Absolute position in known area
Vision systems	Relative position/velocity
Acoustic Doppler current profiler	Relative water velocity

- magnetic north with an accuracy of less than 1° if carefully calibrated to compensate for magnetic disturbances from the vehicle itself. Tables or models can be used to convert from magnetic north to geodetic north.
- **Gyroscope:** The term gyroscope, or gyro, is the name given generically to any instrument measuring inertial angular rotation. Those are based on inertial properties of a vibrating mass or of light. Very accurate gyros may output signal that, when integrated, give heading information with a small enough drift for practical purposes.
 - **Inertial measurement unit (IMU):** An IMU provides information about the vehicle’s linear acceleration and angular velocity. These measurements are combined to form estimates of the vehicle’s attitude including an estimate of geodetic (true) north from the most complex units. In most cases, for slow-moving underwater vehicles, an independent measurement of the vehicle’s velocity is also required to produce accurate estimates of the translational velocity or relative displacement.
 - **Depth sensor:** Measuring the water pressure gives the vehicle’s depth. At depths beyond a few hundred meters, the equation of state of seawater must be invoked to produce an accurate depth estimate based on the ambient pressure [51.23]. With a high-quality sensor, these estimates are reliable and accurate, giving a small error of order 0.01%.

- **Altitude and forward-looking sonar:** These are used to detect the presence of obstacles and distance from the seafloor.
- **Doppler velocity log (DVL):** By processing reflected acoustic energy from the seafloor and the water column from three or more beams, estimates of vehicle velocity relative to the seafloor and relative water motion can be obtained. Bottom-tracking velocity estimates can be accurate to ≈ 1 mm/s.
- **Global navigation satellite system (GLS):** This is used to localize the vehicle while on the surface to initialize or reduce drift of estimates from an IMU/DVL combination. GNSS, such as GPS or Galileo, only works at the surface.
- **Acoustic positioning:** A variety of schemes exist for determining vehicle position using acoustics. Long-baseline navigation can determine the position of the vehicle relative to a set of acoustic beacons anchored to the seafloor or on the surface through range estimates obtained from acoustic travel times. Ultrashort-baseline navigation uses phase information to determine direction from a cluster of hydrophones; this is most often used to determine the direction of the vehicle (in two dimensions) from a surface support vessel, which is then combined with an acoustic travel-time measurement to produce an estimate of relative vehicle position in

Fig. 51.4 The fully actuated AUV ODIN (courtesy of Autonomous Systems Laboratory, University of Hawaii [51.24])

Table 51.6 JHUROV instrumentation

Measured variable	Sensor	Precision	Update rate
3-DOF vehicle position	SHARP acoustic transponder	0.5 cm	10 Hz
Depth	Foxboro/ICT model n. 15	2.5 cm	20 Hz
Heading	Litton LN200 IMU Gyro	0.01°	20 Hz
Roll and pitch	KVH ADGC	0.1°	10 Hz
Heading	KVH ADGC	1°	10 Hz

Table 51.7 ODIN III sensors summary

Measured variable	Sensor	Update rate
xy vehicle position	8 sonars	3 Hz
Depth	Pressure sensor	30 Hz
Roll, pitch, and yaw	IMU	30 Hz

spherical coordinates. These techniques will be discussed later in the localization section.

- **Vision systems:** Cameras can be used to obtain estimates of relative, and in some cases absolute, motion using a type of simultaneous localization and mapping (SLAM) algorithm [51.25] and used to perform tasks such as visual tracking of pipelines, station keeping, visual servoing or image mosaicking.

As an example, Table 51.6 reports some data from the instrumentation of the ROV developed at the John Hopkins University [51.26], and Table 51.7 some data from the AUV ODIN III [51.27] shown in Fig. 51.4. Majumder et al. [51.28] show some data fusion results with a redundant sensorial system mounted on the AUV Oberon, while [51.29] reviews advances in navigation technology.

51.2.3 Actuating Systems

Marine vehicles are generally propelled by means of thrusters or hydrojets. In the case of ROVs with structural pitch–roll stability, there are usually four thrusters that provide holonomic mobility to the four remained DOFs, in particular, the depth is often decoupled and the vehicle is controlled on a plane in the surge, sway, and yaw DOFs. Those vehicles, being underactuated, cannot easily be used for interactive control by means of a manipulator due to the impossibility of counteracting the generalized forces exchanged with the manipulator's base; in such case, six or more thrusters are required. AUVs generally have a torpedo-like shape and are used for mapping/exploration. They are propelled using one or two thrusters parallel to the fore–aft direction and a fin and a rudder; this kind of propulsion is obviously nonholonomic and experiences a loss of mobility at low velocities. Hydrojets, also known as pump jets or water jets, are systems that create a jet of water for propulsion; they have certain advantages over thrusters such as a higher power density and usability in shallow water, but can provide thrust in one direction only.

Several efforts have been made to accurately and efficiently describe the mathematical model of a thruster; [51.30] reports a *one-state* model where the state is n , the propeller shaft speed. In [51.31] a *two-*

state model is proposed to take into account the experimentally observed overshoot in the thrust; together with n , the additional state variable is u_p , the axial flow velocity in the propeller disc. In [51.32] a thruster model incorporating the effects of rotational fluid velocity and inertia on thruster responses is presented together with a method for experimentally determining nonsinusoidal lift/drag curves. A *three-state* model is described in [51.33]

$$\begin{aligned} J_m \dot{n} + K_n n &= \tau - Q, \\ m_f \dot{u}_p + d_{f0} u_p + d_f |u_p| (u_p - u_a) &= T, \\ (m - X_{\dot{u}}) \dot{u} - X_{uu} u - X_{u|u}|u| &= (1 - t)T, \end{aligned}$$

where J_m is the moment of inertia for the dc-motor/propeller, K_n is the linear motor damping coefficient, τ is the motor control input, Q is the propeller torque, m_f is the mass of water in the propeller control volume, u_p is the axial flow velocity in the propeller disc, d_{f0} and d_f are the linear and quadratic damping coefficients for control volume, respectively, u_a is the ambient water velocity, T is the propeller thrust, and t is the thrust deduction number (Fig. 51.5). In the case of steady-state motion, i.e., $\dot{u} = 0$, the ambient water velocity u_a is related to the surge by the *wake fraction number* w as

$$u_a = (1 - w)u. \quad (51.28)$$

Notice also that the unmeasured variable u_p can be estimated using a nonlinear observer [51.33].

The *outputs* of the nonlinear three-state dynamic systems are the thrust T and the torque Q , which are functions of several variables; in the following, unsteady flow effects such as air suction, cavitation, the in-and-out-of-water (Wagner), boundary layer, and

Fig. 51.5 Ambient water and axial flow velocities affecting thruster behavior

gust (Kuessner) effects will be neglected. This leads to a quasi-steady representation of the model

$$T = \rho D^4 K_T(J_0) n |n|, \quad (51.29)$$

$$Q = \rho D^5 K_Q(J_0) n |n|, \quad (51.30)$$

where D is the propeller diameter and $K_T(J_0)$ and $K_Q(J_0)$ are the thrust and torque coefficients, respectively. The latter are function of the advance ratio J_0

$$J_0 = \frac{u_a}{nD}. \quad (51.31)$$

The open-water propeller efficiency in undisturbed water is given as the ratio of the work done by the propeller in producing a thrust force divided by the work required to overcome the shaft torque

$$\eta_0 = \frac{u_a T}{2\pi n Q} = \frac{J_0}{2\pi} \cdot \frac{K_T}{K_Q}. \quad (51.32)$$

Figure 51.6 shows the values of K_T , K_Q , and η_0 as functions of the advance ratio for the Wageningen B4-70 propeller [51.34].

Controlling a marine vehicle usually requires that desired forces/moments act on the vehicle's body; these generalized forces are mapped into desired thrusts to be provided by the propellers. There is, thus, a nontrivial control problem in that the motors are required to provide the appropriate propeller shaft speed n that satisfies the nonlinear relationship with the thrust T presented above.

To enable robustness with respect to possible failures, the actuating system is often redundant. In

this case, the problem of allocation of the desired force/moment acting on the vehicle among the thrusters must also be solved. Reference [51.35] reports a survey of control allocation methods of ships and underwater vehicles.

51.2.4 Communication Systems

Autonomous underwater vehicles may require to communicate with a remote operator or with a base station for monitoring purposes. In case of coordinated mission among several AUVs a network of vehicles/modes communicating among them need to be developed.

Due to the physical characteristics of the water, the more diffused communication technology is based on acoustic propagation. However, the performance of acoustic modems are not as efficient as their aerial counterparts. Three main factors affect the acoustic propagation: a low speed of sound (≈ 1500 m/s), the presence of time-varying multiple paths, an attenuation increasing with the frequency. Finally, the channel capacity is function of the distance and is limited [51.36]. For such a challenging communication medium, efficient communication protocols need to be properly designed [51.37].

51.2.5 Mission Control System

The mission control system (MCS) can be considered as the highest-level process running during an AUV's mission; it is responsible for achieving several control objectives. At the highest level it works as an interface between the operator, accepting his instructions in a higher-level language and decomposing those instructions into mission tasks according to the implemented software architecture. The mission tasks are generally concurrent and their handling depends on the vehicle state and environmental conditions; it is therefore the MCS that handles the tasks, eventually suppressing, sequencing, modifying, and prioritizing them. An MCS is also usually equipped with a graphical user interface (GUI) to report the mission state to the operator, see, e.g., the Neptus Command and Control Infrastructure in [VIDEO 324](#).

As for most advanced robotics applications, an efficient MCS should allow the use of complex robotic systems by users that do not necessarily know all of their technical details. An overview relevant to underwater mission control is given in [51.38], which includes an interesting classification of the MCSs in use in several laboratories according to which four major AUV control architectures were identified: the hierarchical, heterarchical, subsumption, and hybrid.

Fig. 51.6 Values of K_T (solid), $10K_Q$ (dotted), and η_0 (dash-dotted) as a function of J_0 (after [51.34])

From a mathematical point of view, the **MCS** generally needs to be designed in order to be able to address hybrid dynamical systems, i.e., handling both event-driven and time-driven processes. In [51.39], e.g., the **MCS** developed at the Portuguese Instituto Superior Técnico (**IST**), named CORAL, is implemented by resorting to a Petri-net-based architecture that properly handles all the necessary tasks in order to manage navigation, guidance and control, sensing, communications, etc.

The motion-oriented operating system (**MOOS**), designed at the Massachusetts Institute of Technology, is a software tool capable of executing and coordinating a multitude of subsea operations. The **MCS** developed at the Naval Postgraduate School is in the framework of the behavioral control organized in three layers [51.40]; it is based on **PROLOG**, an artificial intelligence language for predicate logic.

51.2.6 Guidance and Control

The terms guidance and control can be defined as [51.8]:

- **Guidance** is the action of determining the course, attitude, and speed of the vehicle, relative to some reference frame (usually the Earth), to be followed by the vehicle.
- **Control** is the development and application to a vehicle of appropriate forces and moments for operating point control, tracking, and stabilization. This involves designing the feedforward and feedback control laws.

Figure 51.7 shows the corresponding block diagram, in which the navigation component is also outlined.

Guidance of Underwater Vehicles

Guidance algorithms may benefit from a wide range of inputs, overall mission information, real-time operator input, environmental measured data such as the ocean current, environmental topological information such as a bathymetric map, exteroceptive sensors for obstacle avoidance, and obviously the vehicle state as output from the navigation system.

The vehicle may be required to follow a path, i.e., a curve geometrically represented in two or three dimensions, or a trajectory, i.e., a path with a specific time law assigned. Moreover, when the desired position is constant, the problem is called set-point regulation or maneuvering. The guidance problem is commonly decomposed into simple subtasks of lower dimension: an attitude control problem and a path control. Moreover, attitude is usually considered as a simple depth set-point with null roll and pitch and the path is usually a line in the horizontal plane.

One of the most common guidance approaches is based on the generations of way-points. Those are usually stored in a database and are used to generate the vehicle path/trajectory; a *passing* velocity, in fact, may be defined together with the Cartesian coordinates of the points. The simplest way to connect the way-points is to use the segments connecting two successive way-points. Efficient way-point-based guidance approaches need to take into account the presence of the current and the eventual nonholonomicity of the vehicle [51.41]. A technique for adaptively tracking bathymetric contours by proper generation of way-points is presented in [51.42]; environment information is acquired by mean of a single vertical sonar. An alternative method is based on *line-of-sight* guidance [51.43–45]. In this case, the heading control is computed by considering as input the angle formed by the vector from the vehicle to the next way-point rather than requiring the vehicle to

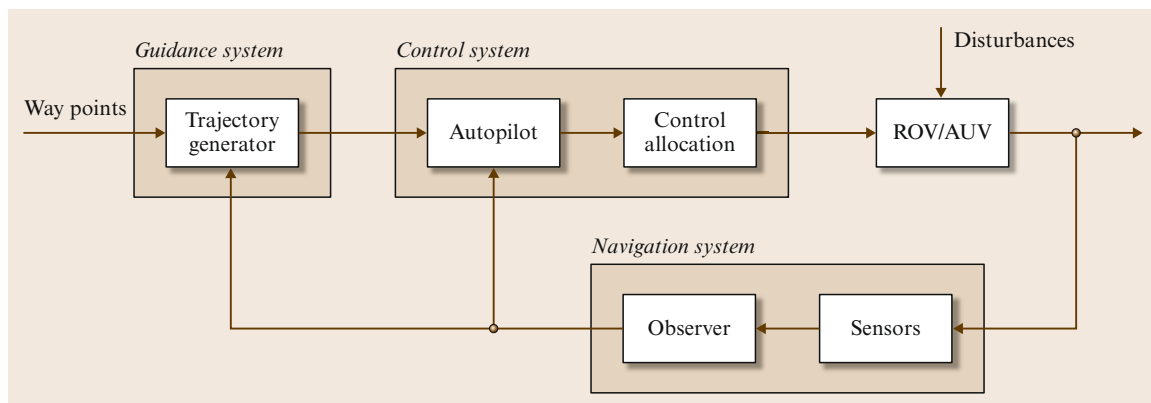

Fig. 51.7 Guidance, navigation, and control for an autonomous marine vehicle

exactly follow the line segment between the current and the following way-point. For docking maneuvers, algorithms must enable control that meets the precision and alignment constraints of the docking fixture [51.46].

By combining vision-based guidance with a neuro-controller trained by reinforcement learning, in [51.47], an algorithm aimed at a hold station on a reef or swimming along a pipe has been presented. In [51.48] guidance for AUVs specifically involved in a pre-deployment survey of the sea bottom and visual inspection of pipelines is given. *Hyland and Taylor* [51.49] report a specific guidance system aimed at mine avoidance for AUVs. Based on a three-dimensional discretization of the environment, the path-planning technique consists of computing a safe path avoiding the unsafe cells of the map. Due to the poor manoeuvrability at low speed under some conditions, the vehicle has to make a 360° turn to avoid stopping and to map the environment close to it before generating a safe path.

A deep discussion on guidance for surface and underwater vehicles can be found in [51.4, 8].

Control of Underwater Vehicles

Control of underwater vehicles needs to consider the different operating conditions and actuating configurations in which a submerged vehicle is required to operate. In particular, there are three main control problems:

- An AUV traveling at high speed (> 1 m/s) generally equipped with at least one thruster aligned in the fore-aft direction and at least two control surfaces (stern and rudder).
- An underactuated ROV, with high metacentric stability, i.e., structurally stable in roll and pitch, and equipped with at least four thrusters.
- A fully actuated AUV equipped with at least six thrusters.

AUVs equipped with control surfaces are under-actuated vehicles mainly used for survey/exploration missions. Inheriting the common practice of submarine control, they are not allowed to perform arbitrary motions in six DOFs but are rather designed to perform specific movements such as: cruising along a given direction at constant depth, steering at constant depth, or diving. Marine experience and mathematical insight, in fact, demonstrate that these movements are lightly coupled in dynamic terms. For these vehicles, moreover, specific manoeuvres such as homing or docking require special capabilities [51.46]. This requires the design of vehicles that are structurally stable in the roll DOF. Cruising requires control of the surge velocity $u(t)$; steering requires control of the sway velocity $v(t)$ and the yaw DOF $r(t)$, $\psi(t)$, diving requires control of

the heave DOF $w(t)$, $z(t)$ and the pitch DOF $q(t)$, $\theta(t)$. The simplest configuration of actuators that can control an AUV through these movements is composed of one thruster aligned along the fore-aft direction, one stern, and one rudder; the control variables, thus, are the propeller speed and the deflection of the fins. Several approaches can then be considered to solve this control problem, among them, in [51.50] the sliding mode control is proposed, while [51.51] presents an adaptive sliding mode control for the diving manoeuvre. *Healey and Lienard* [51.18] reports a successful implementation of multivariable sliding mode control on the NPS AUV II, later also implemented on the NPS ARIES AUV [51.52]. As the model of an AUV traveling at high speed is nonlinear and coupled, the tuning of the parameters is mainly based on a linearized model around the working conditions.

From a descriptive point of view, an ROV is mainly a box-shaped underwater vehicle equipped with tools such as a video camera or robot manipulator, while its payload is often variable depending on the task. It is remotely operated and physically connected to another vehicle, either an underwater or a surface vessel. It is mainly designed to travel at low speed and it is structurally stable in roll and pitch, while its depth, surge, sway, and yaw are independently controllable. Due to the absence of a specific shape, the varying payload, and the relatively low required performances, it is common to control a ROV by means of single-input single-output (SISO) controllers. Moreover, the PID approach is often used due to its simplicity. A two-layer guidance and control architecture for the ROV Romeo is given in [51.53].

Control of a fully actuated AUV in six DOFs is needed in the case of, e.g., an interaction task performed by a manipulator mounted on a vehicle; the latter, in fact, needs to provide all the force/moment components in order to counteract the presence of the manipulator dynamically. This problem is kinematically similar to the problem of controlling a satellite in six DOFs; the underwater environment, however, makes it significantly different from the dynamic point of view. In kinematic terms the main issue is in implementing a suitable policy for orientation control; any three-parameter representation of orientation, in fact, experiences representation singularities (Chap. 2). This problem may be overcome by resorting to a redundant representation of the orientation such as the quaternion. Most of the six-DOF controllers proposed in the literature are based on (51.16), which model the simplified effect of the hydrodynamic terms and which have very similar properties as the equations of motion of an industrial manipulator. Based on this, it is obviously possible to find a collection of approaches inherited

from classical robotics, [51.4, 8] for some examples. In [51.54], some specific considerations for the underwater environment lead to a quaternion-based, adaptive controller; it is worth noticing that adaptive control requires a suitable, and simplified, expression for the hydrodynamic terms. In [51.55] a comparison among several 6-DOF controllers is made.  VIDEO 267 and  VIDEO 268 show two controllers validation implemented in a pool.

51.2.7 Localization

Localization in the underwater environment can be a complex task, mainly due to the absence of a single external sensor that gives the vehicle position such as, e.g., the GPS for outdoor ground vehicles; moreover, the environment is often poorly structured.

One of the most reliable methods is based on the use of acoustic systems such as the baseline systems: the long-baseline system (LBL), the short-baseline system (SBL), and the ultrashort-baseline system (USBL). These systems are based on the presence of a transceiver mounted on the vehicle and a variable number of transponders located in known positions. The transceiver's distance from each transponder can be measured via the measurement of an echo delay; from this information the position of the vehicle can be calculated by basic triangulation operations [51.56]. The USBL can be used with a single transponder, which is usually mounted on a surface ship whose position is measured by GPS. Recent works are aimed at developing localization algorithms based on a single beacon, i.e., range-only measurement among vehicles and buoys [51.57].

Another localization system is called terrain-aided navigation and is based on the use of terrain elevation maps; bathymetric maps are available, especially in the case of well-known locations such as harbors where they usually have a resolution of ≈ 1 m. In this case, the vehicle position is obtained by filtering the information coming from a downward-looking sonar. In [51.58], a particle filter approach was used to localize an AUV in Sydney harbor.

Moving vehicles may be equipped with an IMU or DVL in order to measure its velocity and/or acceleration. This data can then be integrated to estimate the vehicle position. This kind of information is subject to the drift phenomenon and may not be reliable for long-duration runs or may become cost ineffective if accurate IMU devices are needed.

Relative localization can be obtained by resorting to any device that provides information about the relative position of the vehicle with respect to the environment, even in the absence of a map. In this case, by

filtering the distance measurements taken along the motion, the vehicle's position can be measured. This is the case, e.g., of sonar or vision-based localization techniques [51.59].

Often, the techniques presented above are used together in a redundant system and the effective position is obtained by resorting to sensor fusion techniques such as the Kalman filtering approach.

Simultaneous Localization and Mapping

Simultaneous localization and mapping (SLAM), also known as concurrent mapping and localization (CML), is a wide topic in mobile robotics. The problem can be formulated as the requirement for a mobile robot to be placed in an unknown environment and progressively build a map while locating itself inside the map. Chapter 46 discusses this topic in detail. For the marine environment an additional issue arises due by the large-scale map that needs to be used for long-duration missions; [51.60] implements a decoupled stochastic mapping to handle this computational problem in an extended Kalman filter. Terrain-aided navigation with the use of a scanning sonar is implemented in [51.61]. Newman and Leonard [51.62] use long-baseline range measurements as the input for a nonlinear least-squares approach solved by the Gauss–Newton method; both the initially unknown position of the transponders and the vehicle position are estimated. An interesting survey on navigation and SLAM for underwater vehicles is given in [51.29].

51.2.8 Underwater Manipulation

A manipulator may be mounted on an AUV or a ROV in order to accomplish interaction operations. In this case, the vehicle needs to be fully actuated to counteract the forces and moments generated by the manipulator's base. By considering a manipulator with n links, thus six DOFs, the underwater vehicle manipulator system (UVMS) is a $(6+n)$ -DOF robotic system whose velocity vector is

$$\dot{\xi} = (\nu_1^T \ \nu_2^T \ \dot{q}^T)^T, \quad (51.33)$$

where $q \in \mathbb{R}^n$ is the vector collecting the manipulator joints positions.

Repeating the same considerations as for an underwater vehicle, it is possible to write the equations of motions of an UVMS in matrix form as

$$\mathbf{M}(q)\dot{\xi} + \mathbf{C}(q, \xi)\xi + \mathbf{D}(q, \xi)\xi + \mathbf{g}(q, \mathbf{R}_B^I) = \tau, \quad (51.34)$$

where $\mathbf{M} \in \mathbb{R}^{(6+n) \times (6+n)}$ is the inertia matrix, including added mass terms, $\mathbf{C}(q, \xi)\xi \in \mathbb{R}^{6+n}$ is the vector of

the Coriolis and centripetal terms, $\mathbf{D}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} \in \mathbb{R}^{6+n}$ is the vector of dissipative effects, and $\mathbf{g}(\mathbf{q}, \mathbf{R}_I^B) \in \mathbb{R}^{6+n}$ is the vector of gravity and buoyancy effects. The relationship between the generalized forces $\boldsymbol{\tau}$ and the control input is given by

$$\boldsymbol{\tau} = \begin{pmatrix} \boldsymbol{\tau}_v \\ \boldsymbol{\tau}_q \end{pmatrix} = \begin{pmatrix} \mathbf{B}_v & \mathbf{0}_{6 \times n} \\ \mathbf{0}_{n \times 6} & \mathbf{I}_n \end{pmatrix} \mathbf{u} = \mathbf{B} \mathbf{u}, \quad (51.35)$$

where $\mathbf{u} \in \mathbb{R}^{p_v+n}$ is the vector of the control input. Notice that, while for the vehicle a generic number $p_v \geq 6$ of control inputs is assumed, for the manipulator it is supposed that n joint motors are available.

Under this hypothesis, which can be considered as reasonable at low velocity, it holds that:

- The inertia matrix \mathbf{M} of the system is symmetric and positive definite.
- For a suitable choice of the parametrization of \mathbf{C} and if all the single bodies of the system are symmetric, $\dot{\mathbf{M}} - 2\mathbf{C}$ is skew symmetric.
- The matrix \mathbf{D} is positive definite.

In [51.20] the mathematical model written with respect to the Earth-fixed-frame vehicle position and the manipulator end-effector can be found. However, it must be noted that, in this case, a six-dimensional manipulator is considered in order to have a square Jacobian to work with; moreover, kinematic singularities need to be avoided.

The equations of motion of UVMSs in matrix form presented in (51.34) are formally similar to the equations of motion of ground fixed manipulators (Chap. 3) for which a wide control literature exists. This has suggested a suitable translation/implementation of existing control algorithms. However, some differences, crucial from the control aspect, need to be underlined. UVMSs are complex systems characterized by several strong constraints:

- Uncertainty in the model knowledge, mainly due to the poor knowledge about the hydrodynamic effects
- The complexity of the mathematical model
- The kinematic redundancy of the system
- The difficulty in controlling the vehicle in hovering, mainly due to poor thruster performance
- The dynamic coupling between the vehicle and the manipulator
- The low bandwidth of the sensor readings.

In 1996 McLain et al. [51.63] presented a control law for UVMSs with some interesting experimental results conducted at the Monterey Bay Aquarium Research Institute (MBARI). A one-link manipulator was

Fig. 51.8 An underwater vehicle-manipulator system (courtesy of FP7-TRIDENT Project Consortium)

mounted on the OTTER vehicle controlled in all six DOFs by means of eight thrusters. A coordinated control system was then implemented to improve the tracking errors of the end effector.

The monograph [51.64] is focused on the modeling and control issues of such systems, and can be considered as a reference for further reading. Moreover, interaction with the environment is also discussed.

Currently, remotely operated manipulator are standard equipment for several underwater ROVs. However, autonomous manipulation is still a research challenge. The SAUVIM vehicle, developed at the Autonomous Systems Laboratory, University of Hawaii, one of the first semiautonomous underwater vehicle manipulator systems. Similar research projects, ALIVE and TRIDENT were funded by the Framework Program of the European Community [51.2]. Figure 51.8 reports the UVMS developed under the TRIDENT project [51.3].  **VIDEO 89** shows a sampling performed with the Nereus arm.

51.2.9 Fault Detection/Tolerance

Generally, AUVs must operate over long periods of time in unstructured environments in which an undetected failure could cause the loss of the vehicle. Failure detection and a fault-tolerant strategy are required to determine whether a mission must be terminated in the safest manner possible or if the vehicle can continue in a diminished capacity. An example is the case of the arctic mission of Theseus [51.65].

In the case of the use of ROVs, a skilled human operator is in charge of commanding the vehicle; a failure detection strategy is then of help in the human decision-making process. Based on the information detected, the operator can decide on vehicle rescue or to terminate the mission by, e.g., turning off a thruster.

Fault detection is the process of monitoring a system in order to recognize the presence of a failure; fault isolation or diagnosis is the capability to determine which specific subsystem is subject to failure. Often in the literature there is a certain overlap in the use of these terms. Fault tolerance is the capability to complete the mission in the case of the failure of one or more subsystems; it is also known as fault control, fault accommodation, or control reconfiguration. In the following the terms fault detection/tolerance will be used.

The characteristics of a fault detection scheme are the capability to isolate the detected failure, sensitivity in terms of the magnitude of the failure that can be detected, and robustness in the sense of the capability to continue working properly in non-nominal conditions. The requirements of a fault-tolerant scheme are reliability, maintainability, and survival. The common concept is that, to overcome the loss of capability due to a failure, a kind of redundancy is required in the system.

In this section, a survey of existing fault-detection and fault-tolerant schemes for underwater vehicles is presented. For these specific systems, if proper strategies are applied, a hardware/software (HW/SW) sensor or thruster failure can be successfully handled. In some conditions, the fault-detection scheme must also be able to diagnose some external abnormal working conditions such as a multipath phenomena affecting the echo-sounder system. It is worth noticing that, for autonomous systems such as AUVs, space systems or aircraft, a fault-tolerant strategy is necessary to safely recover the damaged vehicle and, obviously, there is no *panic button* in the sense that the choice of turning off the power or activating some kind of brake is not available.

Most fault-detection schemes are model based [51.66, 67] and consider the dynamic relationship between the actuators and vehicle behavior or the specific input–output thruster dynamics. In general, fault-detection/tolerance theory has been applied to the specific case of the underwater environment even if only a few papers report experimental results; see [51.68] for a survey on this topic.

Most fault-tolerant schemes consider a thruster-redundant vehicle that, after a fault has occurred in one of its thrusters, is still actuated in six DOFs. Based on this assumption a reallocation of the desired forces on the vehicle over the working thrusters is performed [51.69]. Of interest is also the study of reconfiguration strategies if the vehicle becomes underactuated.

Possible Failures

Underwater vehicles are currently equipped with several sensors in order to provide information about their

localization and velocity. The problem is not easy. No single, reliable sensor is available that gives the required position/velocity measurement, or information about the environment such as the presence of obstacles. For this reason the use of sensor fusion by, e.g., a Kalman filtering approach, is a common technique to provide the controller with the required variables. This structural redundancy can be used to provide fault-detection capabilities to the system.

For each of the sensors listed in Sect. 51.2.2 failure can consist of an output of zero if, e.g., there is an electrical trouble, or a loss of meaning. It can be considered as sensor failure also an external disturbance such as a multipath reading of the sonar that can be interpreted as a sensor fault and correspondingly detected.

Thruster blocking occurs when a solid body is present between the propeller blades. It can be checked by monitoring the current required by the thruster. This was observed, e.g., during the Antarctic mission of Romeo [51.70], in that case caused by a block of ice. During the same mission a thruster also flooded with water. The consequence was an electrical dispersion, causing an increasing blade rotation velocity and thus a thruster force higher than desired.

A possible consequence of different failures of the thrusters is the zeroing of the blade rotation. The thruster in question thus simply stops working. This has been intentionally experienced during experiments with, e.g., ODIN [51.67, 69], Roby 2 [51.66], and Romeo [51.70].

Other failures include a hardware/software crash or the occurrence of fin sticking or loss. A very common type of failure involves the loss of electrical isolation due to seawater intrusion into underwater electrical cables or connectors. Such a condition can be detected through a technique called ground-fault monitoring. Should this occur, electrical power must be removed from the affected device.

51.2.10 Multiple Underwater Vehicles

A growing research effort has recently been devoted to developing strategies to design coordinated control for underwater vehicles. The use of multiple AUVs, in fact, might improve overall mission performance as well as provide greater tolerance to failures. Specific applications of this method in the underwater environment might include the naval mine countermeasure problem, harbor monitoring, and inspection, exploration, and mapping of large areas. AUVs might be coordinated with one or more surface vessels or connected to ground or aerial vehicles to form a coordinated network of heterogeneous autonomous robots.

Beside several institutions that have developed simulation packages for multiple-AUV operations, the use of real multiple AUVs is being considered for the adaptive sampling and forecasting plan of the Autonomous Ocean Sampling Network, formed by several research institutions such as (for the robotic components) Caltech, MBARI, Princeton, and WHOI [51.71]. Adaptive sampling is also investigated within the project Adaptive Sampling and Prediction (ASAP) [51.72]. The Australian National University is currently work-

ing on a shoal of small, autonomous robots, named Serafina [51.73]. At Instituto Superior Técnico (IST), work is ongoing on the coordination between an AUV and a catamaran [51.74], i.e., a multirobot system constituted by heterogeneous autonomous vehicles. In [51.75] the cooperation between AUVs and a sensor network is experimentally investigated.  VIDEO 323 and  VIDEO 94 show two examples of multi-vehicle bathymetry mission and multi-vehicle patrolling, respectively.

51.3 Applications

Underwater robots currently play prominent roles in a number of scientific, commercial, and military tasks. Remotely teleoperated vehicles are very well established in all these areas, and are becoming increasingly automated to relieve the burden on human operators and to improve performance. Increasingly, autonomous underwater vehicles are finding application in these areas as well. Presently, AUVs are used almost exclusively for survey work, but sampling and other intervention tasks are becoming more feasible. Additionally, the line between ROVs and AUVs continues to blur, as systems that have the best properties of both evolve.

The offshore oil and gas industry relies heavily on ROVs for installation, inspection, and servicing of platforms, pipelines, and subsea production facilities. As the search for oil and gas goes deeper, this trend can only continue. The Marine Technology Society estimates that there are over 435 *work-class* ROVs operating in the commercial offshore industry today. AUVs are now beginning to appear in the commercial offshore industry for survey tasks, and concepts for hybrid systems that can perform intervention tasks are now appearing. The goal is not only for these robotic vehicles to replace human divers or human-occupied vehicles, but to enable an entire new generation of subsea equipment that is serviced without intervention by drill ships or other heavy-lifting vessels. This holds the prospect of greatly reduced cost.

Scientific demand for ROVs and AUVs is also increasing dramatically. Scientific applications for ROVs include survey, inspection, and sampling tasks previously performed by human-occupied submersibles or towed vehicles. While ROVs operating for science are not nearly as numerous as those in the offshore oil and gas industry, they are becoming commonplace. Most nations involved in global seafloor studies have several vehicles. Like the vehicles for the commer-

cial offshore sector, these vehicles are becoming increasingly automated. High-quality electronic imaging, including high-definition television, is becoming increasingly common. Scientific ROVs are now equipped with sophisticated sampling devices for sampling animals, microbes, caustic hydrothermal vent fluids, and a variety of rock samples. Moreover, ROVs are also used to deploy and operate seafloor experiments, which can involve difficult tasks such as drilling and delicate placement of instruments.

ROVs have also emerged as powerful tools for investigating underwater shipwrecks and other cultural sites. Applications include forensic investigations of modern shipwrecks to determine the cause of sinking, archaeology, and salvage. For archaeology, the goals are the same as for excavation on land: detailed mapping followed by careful excavation. Beyond diver depths, ROVs are the preferred method for these investigations. Great progress has been made in the detailed mapping phase, and capabilities for excavation are evolving. Unfortunately, the same technology also opens the possibility for shipwrecks to be looted for financial gain, which usually results in the loss of the most valuable historical information.

After a long period of skepticism, AUVs are now accepted for scientific tasks. Presently, AUVs most often perform mapping tasks while tended by a vessel. Specific mapping tasks include seafloor bathymetry, sidescan sonar imaging, magnetic field mapping, hydrothermal vent localization, and photo surveys. AUVs have been shown to improve productivity and data quality compared to towed and tethered systems. They have also operated in environments where no other means of gathering data is possible, such as under ice shelves. Likewise, the increasing availability of sophisticated in situ chemical sensors, biological sensors, and mass spectrometers now allows AUVs to build spatial and temporal maps of environmental features that could pre-

viously only be studied by bringing samples back to the laboratory. AUV systems that can dock to subsea nodes to recharge batteries, offload data and receive new instructions are presently being tested.

The military has always been a leader in the development of underwater robotic capabilities. They pioneered ROVs for tasks such as recovering test weapons and deep-sea salvage, and present-day commercial and scientific ROVs have descended directly from these early systems. Likewise, military interests are presently pushing AUV technology very hard. Many different countries operate AUVs for military surveys, gathering environmental data as well as searching for hazards such as mines. An operational success was achieved

in surveying for mines in the Persian Gulf harbor of Umm Qasr using REMUS vehicles. AUVs in development will not only be able to detect mines, but to disable them. Bolder, more innovative concepts are also in development. These include networks of AUVs that can act as extensions of conventional surface vessels and submarines, enabling surveillance over wide areas for extended periods of time at costs far less than could be achieved with conventional surface vessels, submarines, and aircraft. These developments will rely on improvements in acoustic communications, energy systems, sensors, and onboard intelligence that will likely find their way into commercial and scientific practice.

51.4 Conclusions and Further Reading

The underwater environment is extremely hostile for human engineering activities. In addition to high pressures and hydrodynamic forces that are both nonlinear and unpredictable, water is not an appropriate media for electromagnetic communication except at short ranges. This pushes underwater technology to rely on acoustic communication and positioning systems that are characterized by low bandwidth. On the other hand, the ocean is extremely important for numerous human activities from the commercial, cultural, and environmental points of view.

Research on underwater robotic applications is active both from the technological and methodological aspects. The power endurance of commercially AUVs is currently up to 50 h; this will increase as energy-storage devices improve. Improved energy and power capability will enable longer missions, higher speeds, or better/additional sensors such as, e.g., more powerful lighting for underwater video/photography. The current trend for the price of AUVs prices is downward, with more and smaller research institutions building or buying AUVs to enrich their research results; moreover the setup of multiple-AUV systems is becoming cost effective. The goal is to develop fully autonomous, reliable, robust, decision-making AUVs.

There are a number of technology issues that are needed in order to improve AUV capabilities: to increase the underwater bandwidth of current acoustic modems, to increase onboard power to handle larger tools and interact more strongly with the environment, to create AUVs with significant hovering capability to allow better interaction, and to enable easier launch and recovery.

In the near future, the ROV/AUV dichotomy will likely become less prominent, with a variety of systems appearing that have attributes of both systems:

- For offshore oil and gas intervention tasks, a vehicle could transit to the work site as a self-powered, fully autonomous vehicle, then dock to the work site. Utilizing energy and communications infrastructure at the work site, the vehicle could then be operated much like a conventional ROV.
- Battery-operated ROVs can communicate with the surface by very lightweight fiber-optic links, enabling the mobility of an AUV but with a high-bandwidth connection to skilled human operators for complex intervention or scientific sampling tasks.
- Acoustic and optical data links can provide moderate to high communication bandwidths over short ranges, enabling human supervision without any tether restrictions. At longer ranges, more modest acoustic bandwidths are available.

These developments make marine robotics a challenging engineering problem with strong connections to several engineering domains. Sending an autonomous vehicle into an unknown and unstructured environment with limited online communication requires some onboard intelligence and the ability for the vehicle to react in a reliable way to unexpected situations.

A major challenge concerning underwater robotics is the interaction with the environment by means of one or more manipulators. Autonomous UVMSs are still the object of research; the current trend is in developing the first semiautonomous robotic devices, which

might be acoustically operated; moreover, if physically possible, the capability to dock to the structure where the intervention is needed might significantly simplify the control. The final aim might be to develop a completely autonomous UVMS, able to localize the intervention site, recognize the task to be performed, and act on it without docking to the station and without human intervention. This might make it possible to perform missions that are currently impossible such as autonomous archaeological intervention at deep sites. This would also enable the oil and gas industry to significantly decrease costs and risks to humans.

The Marine Systems Simulator [51.76] is a Matlab/Simulink library and simulator for marine systems.

It includes models for ships, underwater vehicles, and floating structures. The library also contains guidance, navigation, and control (GNC) blocks for real-time simulation. A numerical simulator including also the presence of a manipulator has been developed under the TRIDENT project [51.77].

For further reading on the topic of underwater systems, the reader is referred to several survey articles, including [51.6, 29, 35, 38, 68]. Additionally, several journals cover oceanic engineering topics, including robotics aspects. A variety of symposia and workshops have been held on a regular basis. Some books/monographs treating marine robotics are [51.4, 8, 9, 17, 64].

52. Modeling and Control of Aerial Robots

Robert Mahony, Randal W. Beard, Vijay Kumar

Aerial robotic vehicles are becoming a core field in mobile robotics. This chapter considers some of the fundamental modelling and control architectures in the most common aerial robotic platforms; small-scale rotor vehicles such as the quadrotor, hexacopter, or helicopter, and fixed wing vehicles. In order to control such vehicles one must begin with a good but sufficiently simple dynamic model. Based on such models, physically motivated control architectures can be developed. Such algorithms require realisable target trajectories along with real-time estimates of the system state obtained from on-board sensor suite. This chapter provides a first introduction across all these subjects for the quadrotor and fixed wing aerial robotic vehicles.

52.1 Overview

The term *aerial robotics* is often attributed to *Robert Michelson* [52.1], as a term to capture a new class of autonomous and intelligent small flying machines. The quest for autonomy of aerial vehicles goes back almost to the origins of powered flight. The first autopilot for a fixed wing vehicle (the Sperry autopilot) was demonstrated in 1912, only a decade after the first powered flight by the Wright brothers. As early as World War I, the potential for an autonomously stabilized and remotely controlled airplane to be an effective weapon was understood and the Curtis–Sperry flying bomb first demonstrated autonomous unmanned flight in 1918 [52.2]. Autopilot technology was perfected during the 1930s as improving aircraft technology lead

to longer flight times and the need to relieve the pilot from constant attention to flight stability of the vehicle. Autonomous and radio controlled target aircraft were developed in the late 1930s and were extensively used during World War II for training. The German V-1 cruise missile, commonly known as the buzz bomb or doodlebug, was a highly successful autonomous vehicle; its relatively low impact in World War II being due to more British intelligence efforts than to the vehicles capabilities.

Following the World War II, the relative maturity of autopilot technology and airplane construction meant that the construction of unmanned fixed-wing vehicles was straightforward. Remote-controlled heli-

copters, such as the Gyrodyne QH-50 DASH, were developed as early as the 1960s. The Yamaha R-50 and subsequent Yamaha R-Max (Fig. 52.1), was developed during the 1980s and provides a remote controlled commercial aerial platform, with significant onboard autonomy, used primarily for agricultural applications.

Extensive development of fixed-wing autonomous vehicles was held back in the mid-20th century by the difficulty of localizing a vehicle when far from the base station. Indeed, the requirements of navigation systems for cruise missiles developed during the cold war was one of the main drivers for the development of satellite global positioning system (GPS) technology. Full operational capability of the United States GPS system with 24 satellites was declared in April 1995 and it was mandated as a dual-use system (both commercial and military) in 1996. Smaller scale commercial unmanned aerial vehicles were also constrained by the lack of robust and small-scale avionics systems. The availability of small low power computers, the development of microelectromechanical systems (MEMS) that provide affordable and robust Inertial Measurement Units (IMUs), and access to reliable GPS, lead to the beginning of the modern era of nonmilitary UAV and aerial robotic systems in the mid-1990s.

The largest class of commercial and military robotic aerial vehicles fly predominantly in obstacle free airspace. For such vehicles, once the aircraft has taken off, there is no need to employ obstacle avoidance techniques or interact with cluttered three-dimensional environments.

Definition 52.1

An *unmanned aerial vehicle (UAV)* is a system capable of sustained flight with no direct human control and able to perform a specific task.

Fig. 52.1 Autonomous aerial robotic vehicle based on the Yamaha RMAX platform developed in the University of New South Wales, Australia (after [52.3, 4])

Navigation and control of an unmanned aerial vehicle is typically based on stabilizing a reference heading and altitude derived from the error between preset GPS way-points and the present vehicle position using a classical autopilot control system. The sensor suite used for control and navigation is usually a GPS and IMU along with barometric pressure. These sensor suites can be thought of as *proprioceptive* sensors, since they measure the internal state of the vehicle without reference to the external world. The kinds of tasks that UAVs are ideal for include high level surveillance and sensing tasks where the payload sensing suite is separate from the vehicle systems, with applications in agriculture, environmental monitoring, geophysical surveys, search and rescue, and security surveillance, as well as deployment of materials, where once again the payload is separate from the vehicle system, with applications in agriculture, search and rescue, and of course military missions. Such systems are a natural development of traditional flight technology and much of the research and development that goes into these vehicles is undertaken in aerospace departments in universities and aerospace companies.

Definition 52.2

An *aerial robotic vehicle* is an aerial vehicle capable of autonomously interacting with a complex dynamic three-dimensional environment and achieving complex environment-dependent goals.

The nature of the interaction with the environment for an aerial robotic vehicle, means that the presence of *exteroceptive* sensors, those that sense the environment around the vehicle, and how these sensor inputs are integrated into the vehicle guidance is the defining property of such a vehicle. Typical examples of exteroceptive sensors for aerial robotic vehicles are vision systems, laser range finders, acoustic sensors, etc., and external sensor systems such as VICON [52.5] and Optitrack [52.6] systems. The close coupling between the goal of the vehicle, its sensing suite, and the dynamic nature of the environment makes the simple way-point navigation control architecture of an unmanned aerial vehicle unsuitable for aerial robotic vehicles. The kinds of tasks that aerial robotic vehicles are ideal for are small-scale interactive tasks such as inspection of civil infrastructure including dam walls, girders of bridges, industrial pressure vessels; and surveillance tasks such as, inspection of damaged or burning buildings, monitoring of crowds, etc. Future applications may involve aerial manipulation including repair of infrastructure, and material handling in the construction and agricultural industries. Although the flight technology remains important, the sensing and control tasks become cru-

cial in such applications and the development that goes into these vehicles tends to be undertaken in robotics departments in universities and in the growing field of new aerial-robotics start-up companies. The ability to move in three-dimensional space brings new research challenges to the robotics community compared to the wheeled mobile robot technology that has motivated mobile robotics research over the last couple of decades.

52.2 Modeling Aerial Robotic Vehicles

There is already a vast range of aerial vehicle and UAV designs in existence, and there are even more ideas under development by companies and research groups as we write. In one short chapter, we must limit the scope of our presentation to a couple of the key examples. There are two major categories of vehicles that are used as platforms for aerial robotics: small-scale rotor vehicles such as the quadrotor, hexacopter, or helicopter, and fixed wing vehicles. The word *quad* is derived from the Latin *quadrangulum* for a four-sided figure. *Rotor* is derived from the Latin *rotationem* for a rotating object. However, *hexa* is derived directly from Greek for six. *Heli* is derived from ancient Greek *helikos* for spiral, while the term *copter* is derived from the modern term *helicopter*, a combination of *helikos* with the ancient Greek *pteron* for wing. Based on this etymology, we propose the terms *quadrotor* and *hexacopter* to describe the most common modern rotary wing aerial robotic vehicles in preference to the etymological questionable terms quadcopter and hexarotor that are also in common usage in the literature. We will present modeling and control material relevant to these two categories, focusing on the basic structure of the model. We will also focus on vehicles in 500 g–4 kg weight range as this corresponds to the primary general robotics applications where avionics and sensor suites take up the majority of the payload. Other classes of autonomous aerial vehicles that we are unable to cover in this chapter include lighter-than-air vehicles such as blimps and balloons, flapping wing vehicles, ducted fans, and rockets.

52.2.1 Rigid Body Motion of the Airframe

Heavier-than-air aerial robotic vehicles consist of a rigid airframe coupled with aerodynamic mechanisms to generate lift and thrust. For vehicles in the weight range considered, the compactness and structural integrity of the airframe means that there is little flexing of the airframe in normal operation and the rigid-body assumption is an effective model. In this case, the ve-

The term *unmanned aerial system (UAS)* is useful to refer to the combination of the infrastructure, human interfaces, aerial platform, and sensing and control subsystems. It is clear that certain vehicles may spend time operating in either UAV mode or aerial robotic mode and the terms are more useful to describe the way of thinking about the operation of a system rather than classifying a vehicle.

hicle model can be developed based on rigid-body dynamics with exogenous forces and torque generated by an aerodynamic model.

Let $\{e_1, e_2, e_3\}$ be the coordinate axis unit vectors $e_1 = (1, 0, 0)^T$, $e_2 = (0, 1, 0)^T$, and $e_3 = (0, 0, 1)^T$ without specification of a frame of reference. Let $\{B\}$ be a (right-hand) body fixed frame for the airframe with unit vectors $\{b_1, b_2, b_3\}$ where these vectors are the axes of frame $\{B\}$ with respect to frame $\{A\}$ as shown in Fig. 52.2. Note that the convention for choice of axes shown in Fig. 52.2 is the convention common in the aerial robotics community [52.7–14], but is opposite to the usual convention in the aerospace community where the b_2 and b_3 axes are usually reversed in order so that b_3 points down in the direction of gravity. In this chapter, we have chosen to follow the robotic community convention and this will lead to some nonconventional definitions for the modeling of fixed-wing airplanes. We will discuss this further in the specific sections on fixed-wing airplane modeling and control.

The orientation of the rigid body is given by a rotation matrix ${}^A R_B = R = [b_1, b_2, b_3] \in \text{SO}(3)$ in the spe-

Fig. 52.2 The body-fixed frame and the directions of rotation for the propellers

cial orthogonal group. We have $\mathbf{b}_1 = R\mathbf{e}_1$, $\mathbf{b}_2 = R\mathbf{e}_2$, $\mathbf{b}_3 = R\mathbf{e}_3$ by construction.

We will use Z-X-Y Euler angles to model this rotation as shown in Fig. 52.3. Note that this is not the normal roll-pitch-yaw convention used in aerospace. To get from $\{A\}$ to $\{B\}$, we first rotate about \mathbf{e}_3 by the yaw angle, ψ , and we will call this intermediary frame $\{D\}$ with a basis $\{\mathbf{d}_1, \mathbf{d}_2, \mathbf{d}_3\}$ where \mathbf{d}_i is expressed with respect to frame $\{A\}$. This is followed by a rotation about the x -axis in the rotated frame through the roll angle, ϕ , to intermediary frame $\{E\}$, followed by a third pitch rotation about the new y -axis through the pitch angle θ which results in the body-fixed triad $\{\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3\}$. The associated rotation matrix is

$$R = \begin{pmatrix} c_\psi c_\theta - s_\phi s_\psi s_\theta & -c_\phi s_\psi & c_\psi s_\theta + c_\phi s_\phi s_\psi \\ c_\phi s_\psi + c_\psi s_\phi s_\theta & c_\phi c_\psi & s_\psi s_\theta - c_\phi c_\theta s_\phi \\ -c_\phi s_\theta & s_\phi & c_\phi c_\theta \end{pmatrix}. \quad (52.1)$$

where c and s are shorthand for cosine and sine, respectively.

Let ξ denote the position of the center of mass of the airframe in frame $\{A\}$ and assume that this is also the origin of frame $\{B\}$. Let $\mathbf{v} \in \{A\}$ denote the linear velocity of $\{B\}$ with respect to $\{A\}$ expressed in $\{A\}$. Let $\Omega \in \{B\}$ denote the angular velocity of $\{B\}$ with respect to $\{A\}$, this time expressed in $\{B\}$. Let m denote the mass of the rigid object and $\mathbf{I} \in \mathbb{R}^{3 \times 3}$ denote the constant inertia matrix (expressed in the body fixed frame $\{B\}$). The rigid body equations of motion of the airframe are [52.15, 16]

$$\dot{\xi} = \mathbf{v}, \quad (52.2a)$$

$$m\dot{\mathbf{v}} = -m\mathbf{g}\mathbf{e}_3 + R\mathbf{F}, \quad (52.2b)$$

Fig. 52.3 The vehicle model. The position and orientation of the robot in the global frame are denoted by ξ and R , respectively

$$\dot{R} = R\Omega_\times, \quad (52.2c)$$

$$\mathbf{I}\dot{\Omega} = -\Omega \times \mathbf{I}\Omega + \tau. \quad (52.2d)$$

The notation Ω_\times denotes the skew-symmetric matrix such that $\Omega_\times v = \Omega \times v$ for the vector cross-product \times and any vector $v \in \mathbb{R}^3$. The vectors $\mathbf{F}, \tau \in \{B\}$ combine the principal nonconservative forces and torques applied to the airframe by the aerodynamics of the propulsion systems and lifting surfaces of the vehicle.

52.2.2 Modeling for Quadrotors

Quadrotors are currently the most popular research aerial robotics research platform because they are highly maneuverable and enable safe and low-cost experimentation in mapping, navigation, and control strategies in three dimensions. They are also arguably the simplest of the aerial robotics platforms to model for robotics applications. Early work in aerial robotics modeling and control dates back to the late 1990s and the field has remained active since [52.15–21].

In its most common form, the quadrotor vehicle is a very simple machine. It consists of four individual rotors attached to a rigid cross airframe as shown in Fig. 52.4. Control of a quadrotor is achieved by differential control of the thrust generated by each rotor. Pitch, roll, and heave (total thrust) control is straightforward to conceptualize. As shown in Fig. 52.2, rotor i rotates anticlockwise (positive about the z -axis) if i is even and clockwise if i is odd. Yaw control is obtained by adjusting the average speed of the clockwise and anticlockwise rotating rotors. The system is under-actuated and the remaining degrees of freedom corresponding to the translational velocity in the \mathbf{b}_1 – \mathbf{b}_2 plane, must be controlled through the system dynamics.

The aerodynamics of rotors was extensively studied during the mid, 1900s with the development of manned helicopters and detailed models of rotor aerodynamics

Fig. 52.4 A quadrotor made by Ascending Technologies at the University of Pennsylvania with Vicon markers for state estimation

are available in the literature [52.22, 23]. Much of the detail in these aerodynamic models is useful for the design of rotor systems where the whole range of parameters (rotor geometry, profile, hinge mechanism, and much more) are fundamental to the design problem. For a typical robotic quadrotor vehicle, the rotor design is a question of choosing one among the several available rotors from the hobby shop and most of the complexity of aerodynamic modeling is best ignored. Nevertheless, a basic level of aerodynamic theory is important to understand the particularities of the control design.

The steady-state thrust generated by a hovering rotor (i.e., a rotor that is not translating horizontally or vertically) in free air may be modeled [52.23, Sect. 2.26] as

$$T_i := C_T \rho A_{r_i} r_i^2 \varpi_i^2, \quad (52.3)$$

where for rotor i , A_{r_i} is the rotor disk area, r_i is the radius, ϖ_i is the angular velocity, C_T is the thrust coefficient that depends on rotor geometry and profile, and ρ is the density of air. In practice, a simple lumped parameter model

$$T_i = c_T \varpi_i^2, \quad (52.4)$$

is used where $c_T > 0$ is modeled as a constant that can be easily determined from static thrust tests.

The reaction torque (due to rotor drag) acting on the airframe generated by a hovering rotor in free air may be modeled as [52.23, Sect. 2.30]

$$Q_i := c_Q \varpi_i^2, \quad (52.5)$$

where the coefficient c_Q (which also depends on A_{r_i} , r_i , and ρ) can be determined by static thrust tests.

As a first approximation, assume that each rotor thrust is oriented in the \mathbf{b}_3 -axis of the vehicle, although we note that this assumption does not hold exactly for a rotor translating through the air.

The total thrust at hover T applied to the airframe is the sum of the thrusts from each individual rotor (Fig. 52.2)

$$T = \sum_{i=1}^4 |T_i| = c_T \left(\sum_{i=1}^4 \varpi_i^2 \right). \quad (52.6)$$

The hover thrust is the primary component of the exogenous force

$$F = Te_3 + \Delta \quad (52.7)$$

in (52.2b) where Δ comprises secondary aerodynamic forces that are induced when the assumption that the rotor is in hover is violated.

The net moment arising from the aerodynamics (the combination of the individual rotor forces) applied to the quadrotor vehicle in directions \mathbf{b}_1 , \mathbf{b}_2 , and \mathbf{b}_3 , respectively, are

$$\begin{aligned} \tau_1 &= c_T d (\varpi_2^2 - \varpi_4^2), \\ \tau_2 &= -c_T d (\varpi_1^2 - \varpi_3^2), \\ \tau_3 &= c_Q \sum_{i=1}^4 \sigma_i \varpi_i^2, \end{aligned} \quad (52.8)$$

where d is the arm length of the quadrotor. A consequence of the structure of the thrust generation and the lack of aerodynamic lifting surfaces for a quadrotor means that one can solve for the heave and torque in a single equation in terms of the motor inputs

$$\underbrace{\begin{pmatrix} T \\ \tau_1 \\ \tau_2 \\ \tau_3 \end{pmatrix}}_F = \underbrace{\begin{pmatrix} c_T & c_T & c_T & c_T \\ 0 & dc_T & 0 & -dc_T \\ -dc_T & 0 & dc_T & 0 \\ -c_Q & c_Q & -c_Q & c_Q \end{pmatrix}}_G \begin{pmatrix} \varpi_1^2 \\ \varpi_2^2 \\ \varpi_3^2 \\ \varpi_4^2 \end{pmatrix}. \quad (52.9)$$

Inverting this relationship provides a mapping from desired control input for the rigid-body dynamics to rotor speed set-points for the motor control.

In practice, there are additional second-order aerodynamic effects present in the thrust generation for quadrotor vehicles [52.17, 19–21]. The principle second-order aerodynamic effects that are present at low speeds are *inflow variation*, *rotor flapping*, and *induced drag*. The first of these effects reduces the heave thrust when the quadrotor is ascending and increases the thrust when it is descending due to variation in rotor inflow velocity caused by the quadrotor motion. This acts as a damping term in the vertical direction of motion for the quadrotor. The remaining two effects generate forces that oppose horizontal translation of the quadrotor; blade flapping by inclining the rotor plane of flexible blade rotors and tilting the thrust vector away from the direction of motion, and induced drag by increasing the drag on the blade of a rigid rotor advancing in the direction of motion of the quadrotor [52.21]. In practice, it is difficult to separate the difference between the various effects and it is sufficient to model them all by a single damping force

$$\Delta = -Dv, \quad (52.10)$$

where D is a diagonally dominant positive definite matrix. For small quadrotors with relatively rigid rotor blades designed for hover performance, that is with

close to ideal chord and ideal twist, these effects are far more significant than is usual in classical helicopters and the effect must be modeled to achieve good control performance. These aerodynamic effects are also important in providing key low-frequency excitation to attitude and velocity estimation in the absence of GPS [52.21, 24–26].

At higher translation speeds, a quadrotor also experiences *translational lift*, *translational drag*, and *parasitic drag*. These aerodynamic effects are associated with efficiency gains in the rotor operation associated with increased inflow velocity generated by the forward velocity of the vehicle. Such effects are extremely important in large scale manned helicopters, which spend much of their time in forward flight. For many robotics applications, however, the vehicle is in quasi-stationary or near hover flight almost all the time and these secondary aerodynamic effects may be ignored. We will not discuss them further in this chapter but refer the interested reader to recent work [52.18, 20] and any of the classical helicopter texts [52.22, 23, 27].

52.2.3 Modeling of Fixed-Wing Airplanes

The conventional model for fixed-wing airplane uses a north-east-down frame of reference. The frame of reference used in this chapter, corresponding to the common aerial robotics convention inherited from the mobile-robotics community, is a north-west-up convention. We will still need to define the usual auxiliary angles associated with fixed-wing modeling and control, in particular; the angle-of-attack, side-slip, aerodynamic-bank, flight-path, and course angles. We will use the normal conventions to define these angles. The north-west-up convention now means that flight-path angle is positive when descending and negative when ascending, and positive roll leads course angle to decrease. The careful reader can easily transform between the conventions used here and the conventional airplane modeling approach and the authors apologize for any confusion that is caused by using a single convention for the whole chapter.

The key difference in modeling fixed-wing airplanes to quadrotors is that they rely on lift generated by airflow over the wings to support them in flight. The angle of incidence of the wind on the wing is a key variable in the dynamics of the vehicle and must be modeled in the dynamics. Since the main lift force is generated by an aerodynamic process, rather than directly by a controlled input as was the case for quadrotors and blimps, the modeling and control of an airplane is somewhat more complicated.

The aerodynamics of a fixed wing vehicle are defined relative to the local wind frame $\{W\}$. Frame $\{W\}$

is chosen co-linear with the inertial frame $\{A\}$, but with linear velocity equal to the average extrinsic wind velocity with respect to the inertial frame. The wind frame is a Galilean frame (moving with constant velocity) with the property that it has zero extrinsic wind on average. Let $v_a \in \{W\}$ denote the aerodynamic velocity of the vehicle, that is the linear velocity of the vehicle in the wind frame $\{W\}$. Let $v_w \in \{A\}$ denote the average wind velocity as measured in the inertial frame $\{A\}$. Since the orientation of frames $\{A\}$ and $\{W\}$ are equal, the inertial velocity of the vehicle can be written as

$$v = v_a + v_w \in \{A\}.$$

To model the incident wind as seen by the vehicle as it flies through the air we introduce the flow frame (also termed the air frame) denoted by $\{F\} = (f_1, f_2, f_3)$ where the orientation vectors $\{f_i\}$ are expressed in the wind frame $\{W\}$ which is co-linear with the inertial frame $\{A\}$. The first axis of the flow frame f_1 is oriented in the direction of the incident wind on the vehicle, f_3 is chosen to lie in the plane of symmetry of the vehicle orthogonal to b_2 , and f_2 makes up the right-hand frame. By construction, the velocity of the vehicle in the flow frame always lies in the direction f_1 .

We define two orientation matrices associated with the wind frame. The angle-of-attack (AOA) matrix ${}^B R_F = R_{\alpha, \beta}$ describes the orientation of the airflow frame $\{F\}$ with respect to the body-fixed-frame $\{B\}$ in terms of the *angle-of-attack* α , and the *side-slip angle* β [52.28] (Fig. 52.5). Using the Z–Y–X Euler angle convention (yaw by β , pitch by α , and there is no roll) we have

$$R_{\alpha, \beta} = \begin{pmatrix} c_\alpha c_\beta & -c_\alpha s_\beta & -s_\alpha \\ s_\beta & c_\beta & 0 \\ s_\alpha c_\beta & s_\alpha s_\beta & c_\alpha \end{pmatrix}. \quad (52.11)$$

Fig. 52.5 Representation of angle-of-attack, side-slip angle, and airspeed. Here v_{air} is denoted by v_a in the text to save space

The second orientation matrix is the flight-path matrix ${}^W R_F = R_{\mu, \gamma, \chi}$ that denotes the orientation of the flow frame $\{F\}$ with respect to the wind frame $\{W\}$ in terms of the *aerodynamic bank angle* μ , the *flight path angle* γ , and the *course angle* χ . Using the Z-Y-X Euler angle convention (yaw by χ , pitch by γ , and roll by μ) we have

$$R_{\mu, \gamma, \chi} = \begin{pmatrix} c_\gamma c_\chi & s_\gamma s_\mu c_\chi - c_\mu s_\chi & s_\gamma c_\mu c_\chi + s_\mu s_\chi \\ c_\gamma s_\chi & s_\gamma s_\mu s_\chi + c_\mu c_\chi & s_\gamma c_\mu s_\chi - s_\mu c_\chi \\ -s_\gamma & c_\gamma s_\mu & c_\gamma c_\mu \end{pmatrix}. \quad (52.12)$$

Note that the frames $\{W\}$ and $\{A\}$ are co-linear so ${}^A R_F = {}^W R_F$. It follows that ${}^W R_F = {}^A R_F = {}^A R_B {}^B R_F$.

Aerodynamic forces generated by lifting surfaces are proportional to the dynamic pressure [52.28]

$$\bar{Q} = \frac{1}{2} \rho |v_a|^2, \quad (52.13)$$

where ρ is the air density and $|v_a|$ represents the air-speed or norm of the velocity v_a . Consider the situation where the aircraft is in normal flight, that is cruising at subsonic velocity while avoiding stall phenomenon. Let S denote the surface area of the wing (or lifting surface of the vehicle). The lift $L = F_Z^a$ generated by the lifting surface is defined as the aerodynamic force oriented in the f_3 direction in flow frame $\{F\}$ and can be modeled as

$$L = \bar{Q} S C_L^\alpha (\alpha + \alpha_0) + \bar{Q} S C_L^\beta \beta \\ \approx \bar{Q} S (C_L + C_L^\alpha \alpha) \quad (52.14)$$

for sufficiently small angle of attack α (typically less than 15°). The terms $C_L^\alpha (\alpha + \alpha_0)$ and $C_L^\beta \beta$ are linear approximations to the lift-coefficient curves for small α and β [52.28]. The offset angle of attack α_0 is thought of as the effective angle of attack of the wing in normal level flight conditions. In particular, at normal cruising speed in level flight, $\bar{Q} S C_L^\alpha \alpha_0 = mg$ is the lift required to sustain the vehicle in level flight, so that $\alpha, \beta = 0$ in level flight. The term $\bar{Q} S C_L^\beta \beta$ is small and can be discarded in many applications.

The drag $D = -F_X^a$ is a combination of parasitic and induced drag and is oriented in the $-f_1$ direction.

$$D = \bar{Q} S [C_D^\rho + \kappa (C_L^\alpha)^2 (\alpha + \alpha_0)^2] \\ \approx \bar{Q} S (C_D + C_D^\alpha \alpha), \quad (52.15)$$

where κ is the *Oswald coefficient* [52.28] and the second equation is obtained by ignoring α^2 terms. The

constant C_D combines the parasitic drag coefficient C_D^ρ along with the induced drag $\kappa (C_L^\alpha)^2 \alpha_0^2$ due to α_0 , while $C_D = 2\kappa \alpha_0 (C_L^\alpha)^2$ is the linear coefficient for the dependence of induced drag on the angle-of-attack. It is also possible to model a contribution $\bar{Q} S C_D^\beta \beta$ to the drag force, however, this is sufficiently small that it is normally ignored. There is a final lateral aerodynamic force component F_Y^a that is due to side-slip

$$F_Y^a = \bar{Q} S C_Y^\beta \beta. \quad (52.16)$$

The propeller or thrust mechanism of a fixed wing vehicle generates thrust T in direction b_x in the body-fixed-frame. The total linear force $F \in \{B\}$ applied to the vehicle due to aerodynamic effects and thrust effects is

$$F = R_{\alpha, \beta} (F_X^a, F_Y^a, F_Z^a)^T + (T, 0, 0)^T \\ = \begin{pmatrix} T \\ 0 \\ 0 \end{pmatrix} + \bar{Q} S \begin{pmatrix} -C_D c_\alpha c_\beta - C_L s_\alpha \\ -C_D s_\beta \\ -C_D s_\alpha c_\beta + C_L c_\alpha \end{pmatrix} \\ + \bar{Q} S \begin{pmatrix} -C_D^\alpha c_\alpha c_\beta - C_L^\alpha s_\alpha \\ -C_D^\alpha s_\beta \\ -C_D^\alpha s_\alpha c_\beta + C_L^\alpha c_\alpha \end{pmatrix} \alpha \\ + \bar{Q} S \begin{pmatrix} -C_D^\beta c_\alpha c_\beta - C_Y^\beta c_\alpha s_\beta - C_L^\beta s_\alpha \\ -C_D^\beta s_\beta + C_Y^\beta c_\beta \\ -C_D^\beta s_\alpha c_\beta + C_Y^\beta s_\alpha s_\beta + C_L^\beta c_\alpha \end{pmatrix} \beta \quad (52.17)$$

expressed in the flow frame.

The aerodynamic moments $\tau \in \{B\}$ in the body-fixed frame are modeled by

$$\begin{pmatrix} \tau^x \\ \tau^y \\ \tau^z \end{pmatrix} = \bar{Q} S l \begin{pmatrix} C_x^\beta \beta + C_x^\rho \frac{c \Omega_x}{2|v_a|} + C_x^r \frac{c \Omega_z}{2|v_a|} + C_x^\delta \delta_x \\ C_y + C_y^\alpha \alpha + C_y^q \frac{b \Omega_y}{2|v_a|} + C_y^\delta (\delta_y + \delta_y^0) \\ C_z^\beta \beta + C_z^r \frac{c \Omega_z}{2|v_a|} + C_z^\delta \delta_z \end{pmatrix}, \quad (52.18)$$

where $(\Omega_x, \Omega_y, \Omega_z)$ are the components of the angular velocity $\Omega \in \{B\}$ and represent the roll, pitch and yaw rates of body-fixed frame, respectively; b is the wing span, c is the mean cord of the wing,

and $(\delta_x, \delta_y, \delta_z)$ are deflections of the airplane control surfaces (ailerons, elevator, and rudder). The constants $\{C_x^p, C_x^r, C_x^\delta, C_y^\alpha, C_y^q, C_y^\delta, C_z^\beta, C_z^r, C_z^\delta\}$ are dimensionless aerodynamic coefficients [52.28]. In normal trim conditions, the trimmed elevator deflection δ_y^0 is chosen to cancel the static moment C_y generated by the wing in level flight, $C_y^\delta \delta_y^0 = -C_y$.

Combining (52.17) and (52.18) with (52.2) yields a dynamic model for a fixed wing vehicle with minimal approximations. The resulting equations of motion are complex and can be difficult to work with directly. The most common approach to control fixed-wing vehicles based on the full model is to take this model and linearize the state equations, either along a trajectory, or in regions of state space. The resulting model is either a linear time-varying or linear parameter varying system and can be controlled using classical linear system control techniques [52.29]. Although this approach is well established in the aerospace industry it tends to hide the underlying structure of the dynamics and requires good models of the various aerodynamic parameters, a challenge for many aerial robots with airframes that are always subject to being fiddled with and having sensor packages attached externally. For aerial robotic applications it is of interest to consider a simplified but still structurally consistent model of fixed wing dynamics and use robust and simple control strategies.

Bank-to-Turn Flight Regime

In this section, we propose a model that is suitable for a wide range of fixed-wing applications where the vehicle is in normal flight mode. The approach taken uses a flight regime where the lateral acceleration required to turn the vehicle is obtained by tilting the lift generated by the wings, a strategy termed *bank-to-turn* or *coordinated turn* in the aerospace literature [52.30, 31]. A bank-to-turn maneuver is characterized by zero sideslip, $\beta = 0$, and leads to considerable simplification of the equations of motion. This is a very common mode of flying for any fixed-wing vehicle and, unless the task requires aerobatic maneuvers or the vehicle lacks control surface actuation, is the natural mode to control a UAV.

Given that accurate measurements of the roll rates Ω are available through an onboard IMU system and most UAV systems have large control surfaces relative to their size, it is possible to use high gain to dominate the attitude dynamics (52.2d) and (52.18). That is, the angular velocity $\Omega \approx \Omega^*$ can be thought of as an input to the reduced order model (52.2a), (52.2b), (52.2c). The above discussion motivates a dynamic reduction of the system equations with new inputs Ω^* , as well as T the propeller thrust.

Based on the assumption that the vehicle is flying using bank-to-turn control and for small angle-of-attack then the approximation $\beta \approx 0$ holds and simplified dynamic equations can be derived. Using this approximation and canceling all second-order terms in α and β allows one to rewrite (52.17) as

$$F = \begin{pmatrix} T \\ 0 \\ 0 \end{pmatrix} + \bar{Q}S \begin{pmatrix} -C_D \\ 0 \\ C_L \end{pmatrix} + \bar{Q}S \begin{pmatrix} -C_D^\alpha - C_L \\ 0 \\ C_L^\alpha - C_D \end{pmatrix} \alpha. \quad (52.19)$$

From the construction of $\{F\}$ we have ${}^v F_a = |v_a|f_1$ by definition. It follows that (52.2a) can be written as

$$\dot{\xi} = v_a = |v_a|R_{\mu,\gamma,\chi}e_1.$$

Note that $R_{\mu,\gamma,\chi}e_1 = (c_\chi c_\gamma, s_\chi c_\gamma, -s_\gamma)^T$ does not depend on the aerodynamic bank angle μ . Thus, $(|v_a|, \gamma, \chi)$ can be used as generalized coordinates for the velocity of the vehicle

$$\dot{\xi} = |v_a|(c_\chi c_\gamma, s_\chi c_\gamma, -s_\gamma)^T. \quad (52.20)$$

Differentiating $v_a = \dot{\xi}$ and rearranging yields

$$\dot{v}_a = R_{\mu,\gamma,\chi} \begin{pmatrix} 1 & 0 & 0 \\ 0 & |v_a|c_\gamma s_\mu & -|v_a|s_\mu \\ 0 & -|v_a|c_\gamma s_\mu & -|v_a|c_\mu \end{pmatrix} \begin{pmatrix} \dot{|v_a|} \\ \dot{\gamma} \\ \dot{\chi} \end{pmatrix}. \quad (52.21)$$

Consider the (3, 2) element of (52.12) and recall that $R_{\mu,\gamma,\chi} = R_{\phi,\theta,\psi}R_{\alpha,\beta}$ and applying $\beta \equiv 0$ then $s_\mu c_\gamma = s_\phi$ and we have

$$s_\mu = \frac{s_\phi}{c_\gamma} \quad (52.22)$$

for normal flight conditions where $c_\gamma \neq 0$ and $s_\phi < c_\gamma$. By simple geometry,

$$c_\mu = \frac{1}{c_\gamma} \sqrt{c_\gamma^2 - s_\phi^2},$$

and the dependence on the bank angle can be removed entirely from kinematics of $(|v_a|, \gamma, \chi)$ to be replaced by the roll angle ϕ .

Inverting (52.21) and substituting for (52.2b), (52.19) and for (52.22) we obtain

$$\begin{aligned} \frac{d}{dt}|v_a| &= -gs_\gamma + \frac{T}{m}c_\alpha - \alpha \frac{\bar{Q}S}{m}(C_D^\alpha + C_L) \\ &\quad - \frac{\bar{Q}S}{m}C_D, \end{aligned} \quad (52.23a)$$

$$\dot{\chi} = -\frac{s_\phi}{c_\gamma} \left(\frac{\bar{Q}S}{mc_\gamma} C_L + (C_L^\alpha - C_D)\alpha \right), \quad (52.23b)$$

$$\begin{aligned} \dot{\gamma} &= \frac{gc_\gamma}{|v_a|} + \alpha \frac{\bar{Q}S}{m}(C_L^\alpha - C_D) \\ &\quad - C_L \frac{\bar{Q}S \sqrt{c_\gamma^2 - s_\phi^2}}{m|v_a|c_\gamma}, \end{aligned} \quad (52.23c)$$

where one should recall that $\bar{Q} = \frac{1}{2}\rho|v_a|^2$ (52.13) depends on $|v_a|$.

Note that for α small, T provides a free input to stabilize the speed of the vehicle in (52.23a), although we have seen in Sect. 52.3.2 that a different approach is advantageous in practice. In (52.23b), there is no direct input variable, however, the roll ϕ will play this role in the control design. Similarly, in (52.23c), the angle-of-attack α , which itself has dynamics, must be used to control γ . In fact, both (52.23b) and (52.23c) depend on a complex mix of variables including dynamic pressure (and consequently $|v_a|$) as well as ϕ , α and γ . Nevertheless, the identification of roll ϕ with control of heading and angle-of-attack α with control of flight path is a natural approach in the development of aircraft control.

The kinematics of ϕ are straightforward to compute by differentiating (52.1). Differentiating the (3, 2) entry of $R_{\phi,\theta,\psi}$ (52.1) we have

$$\dot{\phi} = \Omega_x c_\theta + \Omega_z s_\theta. \quad (52.24)$$

The primary control for $\dot{\phi}$ is the roll angular velocity Ω_x and this control will be used to cancel the disturbance created by Ω_z as discussed in Sect. 52.3.2.

To model the dynamics of α , recall the relationship $R_{\mu,\gamma,\chi} = R_{\phi,\theta,\psi} R_{\alpha,\beta}$ again. This time considering the (3, 1) element of $R_{\mu,\gamma,\chi}$ we obtain

$$\begin{aligned} \dot{\alpha} (c_\phi s_\theta s_\alpha + c_\alpha c_\phi c_\theta) &= \\ &= -s_\phi c_\alpha \Omega_x + s_\phi s_\alpha \Omega_z \\ &\quad + (c_\phi s_\theta s_\alpha + c_\phi c_\theta c_\alpha) \Omega_y \\ &\quad - c_\gamma \dot{\gamma}. \end{aligned} \quad (52.25)$$

Back substituting from (52.23c) and rearranging yields

$$\begin{aligned} \dot{\alpha} &= \Omega_y + \frac{s_\phi s_\alpha \Omega_z - s_\phi c_\alpha \Omega_x}{(c_\phi s_\theta s_\alpha + c_\alpha c_\phi c_\theta)} \\ &\quad - c_\gamma \left[\frac{gc_\gamma}{|v_a|} + \alpha \frac{\bar{Q}S}{m}(C_L^\alpha - C_D) - \frac{\bar{Q}S c_\mu}{m|v_a|} C_L \right], \end{aligned} \quad (52.26)$$

where the denominators are always well defined for normal flight conditions. The angular velocity Ω_y enters (52.26) as a free input providing the control for AOA.

Equations (52.23a), (52.23c) and (52.26) lead to a cascade nonlinear system

$$\dot{\chi} = -s_\phi \left(\frac{|v_a|^2}{c_\gamma^2} A_2 + \frac{\alpha}{c_\gamma} A_3 \right), \quad (52.27a)$$

$$\dot{\phi} = u_\phi, \quad (52.27b)$$

$$\dot{h} = -|v_a| s_\gamma, \quad (52.27c)$$

$$\frac{d}{dt}|v_a| = TA_1 - gs_\gamma + f_1(\gamma, \alpha, |v_a|), \quad (52.27d)$$

$$\begin{aligned} \dot{\gamma} &= \alpha |v_a|^2 A_4 - \frac{|v_a|}{c_\gamma} (c_\gamma^2 - s_\phi^2)^{\frac{1}{2}} A_5 \\ &\quad + f_2(\gamma, |v_a|), \end{aligned} \quad (52.27e)$$

$$\dot{\alpha} = u_\alpha + f_3(\gamma, \alpha, |v_a|; t), \quad (52.27f)$$

with the following constants

$$A_1 = \frac{c_\alpha}{m}, \quad A_2 = \frac{C_L \rho S}{2m}, \quad A_3 = (C_L^\alpha - C_D),$$

$$A_4 = \frac{\rho S}{2m}(C_L^\alpha - C_D), \quad A_5 = C_L \frac{\rho S}{2m},$$

functions;

$$f_1(\gamma, \alpha, |v_a|) = -\alpha \frac{\bar{Q}S}{m}(C_D^\alpha + C_L) - \frac{\bar{Q}S}{m}C_D,$$

$$f_2(\gamma, |v_a|) = \frac{gc_\gamma}{|v_a|},$$

$$\begin{aligned} f_3(\gamma, \alpha, |v_a|) &= -c_\gamma \left[\frac{gc_\gamma}{|v_a|} + \alpha \frac{\bar{Q}S}{m}(C_L^\alpha - C_D) \right. \\ &\quad \left. - \frac{\bar{Q}S c_\mu}{m|v_a|} C_L \right], \end{aligned}$$

and the input functions;

$$u_\phi = \Omega_x c_\theta + \Omega_z s_\theta,$$

$$u_\alpha = \Omega_y + \frac{s_\phi s_\alpha \Omega_z - s_\phi c_\alpha \Omega_x}{(c_\phi s_\theta s_\alpha + c_\alpha c_\phi c_\theta)}.$$

Here the height h kinematics have been added to complete the bank-to-turn dynamics. The course (52.27a), and the height (52.27c) dynamics have negative signs compared to conventional fixed-wing modeling developments due to the nonstandard north-west-up convention chosen.

These equations are fully nonlinear equations based on the sliding mode simplification associated with holding $\beta \equiv 0$. The condition on side-slip angle will can be enforced using the free degree of freedom in Ω_z as will be discussed in Sect. 52.3.2. We note that the dynamics presented in this section are closely related to the *longitudinal dynamics* considered in classical aeronau-

tical texts that treat the angle of attack, glide angle, and velocity of the vehicle. The more classical expressions for longitudinal control of a fixed-wing vehicle are obtained from the above model by setting $\dot{\chi} = \mu = \phi = 0$. An additional simplifying assumption often made for the course kinematics (52.27a) is that lift is compensating gravity during level-flight. With these assumptions, (52.27a) can be replaced by

$$\dot{\chi} = -\frac{g}{|v_a|} \tan(\phi)$$

based on centripetal force balance.

52.3 Control

Control for aerial vehicles is challenging for a number of reasons. First, most aerial vehicles are under actuated and the control design must exploit interactions between dynamic states to control the vehicle. Second, aerial vehicles use aerodynamic effects for thrust and lift generation, and regulation of these forces is by nature approximate, leading to significant modeling error. Third, external effects such as wind, turbulence, and vortex generation, lead to high levels of load disturbance in the control loops. Finally, it is often difficult or impossible to measure the vehicle and aerodynamic state directly making it necessary to use an observer or design the controller from first principles to use explicit measurements.

Most aerial vehicles are controlled using a hierarchical control structure with nested feedback loops based on three levels; planning, guidance, and control:

- **Planning:** It is the outermost loop in aerial vehicle control and is associated with path planning, setting way-points, etc.
- **Guidance:** The guidance level of control concerns tracking trajectories to achieve local goals. This control loop is typically designed using the attitude reference as a virtual input, leading to a fully actuated control problem.
- **Control:** It is the high gain innermost loop of the control hierarchy and is concerned primarily with attitude and flight stability of the vehicle. This control problem is typically fully actuated and can be tackled using standard control techniques.

The more dynamic and aggressive the task considered is, the more these levels of control will interact and an integrated control design must be considered. However, in most real-world situations, splitting the control into three hierarchical levels leads to a simpler design

problem that achieves the desired performance. For example, the recent aggressive maneuvers undertaken and demonstrated in quadrotor control are based on hierarchical control strategies that use trajectory planning processes for the outer loop that specify achievable trajectories that then are stabilized in real-time using attitude as a virtual input, with high-gain feedback on the inner-loop attitude stability control. Most of this work has been done with the use of external motion capture systems to provide the inertial frame position and velocity feedback [52.7–12, 32]. However, more recently there have been a few attempts to do this with on-board cameras and inertial measurement units [52.13, 14].

52.3.1 Quadrotor Control

The quadrotor control and guidance problem is conceptually more straightforward than that of fixed-wing vehicles. In its simplest form, the goal is to design control algorithms to track smooth feasible trajectories $(R^*(t), \xi^*(t)) \in \text{SE}(3)$. We will assume that a planner specifies the full desired trajectory, including the higher order derivative terms $(\Omega^*(t), \dot{\xi}^*(t))$ and $(\ddot{\Omega}^*(t), \ddot{\xi}^*(t))$. A quadrotor vehicle is an under-actuated system – there are four inputs $\mathbf{u} = (T, \tau^T)^T$, while the trajectory lives in $\text{SE}(3)$ and is six-dimensional. The hierarchical control structure proposed leads to an inner loop regulating the attitude using the moments τ as the control input. The guidance level utilizes the attitude R and heave T to regulate the trajectory $\xi(t)$ to track $\xi^*(t)$. In high performance control of a quadrotor, the major limitation to performance comes from the limits of motor response and the control hierarchy must be augmented by a low level motor regulation system. The proposed control architecture forms nested feedback loops as shown in Fig. 52.6.

Fig. 52.6 Typical control architecture. A base-level motor regulation, an inner attitude control loop, an intermediate position guidance loop, with an outer trajectory planner

Motor Regulation

The aerodynamics of thrust generation by rotors is a subject that has been studied in detail in the classical rotorcraft literature [52.22, 23, 27]. Using a full model of rotor aerodynamics has significant potential in the design of the motor control for high-performance rotor control for aerial robotic applications [52.33]. Despite this, it is sufficient in most cases to consider a static thrust model that holds for a rotor in hover and is a reasonable approximation for most robotic applications. In such a model, the thrust generated is proportional to the square of the rotor speed. Since most quadrotor vehicles are equipped with brushless DC motors that use back EMF sensing for rotor commutation, making it possible to measure rotor angular velocity, the control of the rotor thrust is usually implemented as a local control loop on the electronic speed controller (ESC) regulating rotor speed.

Most ESC use PWM (pulse width modulation) regulation of voltage bus to provide voltage control of the motors. A typical rise time for the uncontrolled system is in the order of 200 ms and it is necessary to include a local control loop to improve the system response. The aerodynamic drag of the rotor means that the system is naturally heavily damped and there is no need for derivative control. Similarly, an integral term is rarely deemed necessary at the rotor control level since the thrust model used is not particularly accurate anyway and it will always be necessary to have integral control at higher levels in the control hierarchy. Since an integral term is inadvisable, it is important to use the best model of the thrust generation possible as a feedforward term $V_{ff}(\varpi_i^*)$ to minimize the requirement on the proportional regulation. Thus, a typical ESC rotor control is given by saturated proportional control with feedforward [52.34]

$$V_i = \text{sat} [k(\varpi_i^* - \varpi_i) + V_{ff}(\varpi_i^*)], \quad (52.28)$$

where V_i is the applied motor voltage, ϖ_i^* is the desired speed and the actual motor speed ϖ_i is measured from the electronic commutation in the embedded

speed controller. The performance of the motor controllers is ultimately limited by the current that can be supplied from the batteries [52.34] and a saturation on the demanded voltage is necessary. Without the saturation, extreme maneuvers may cause the voltage bus to drop excessively, destroying the rotor regulation performance and unless care is taken, causing the onboard electronics to brownout.

Attitude Control

The control problem considered in attitude regulation is to use full actuation of τ in (52.2d) to control (52.2c) to track a desired attitude trajectory $R^*(t)$ along with its velocity $\Omega^*(t)$ such that $\dot{R}^*(t) = R^*(t)\Omega^*(t)$. The approach described uses a global stability design based on minimizing the matrix error

$$\tilde{R} = (R^*)^T R \quad (52.29)$$

similar to [52.7, 35]. Driving $\tilde{R} \rightarrow I_3$ ensures that $R \rightarrow R^*$. The kinematics of the tracking error is given by

$$\begin{aligned} \dot{\tilde{R}} &= -\Omega_\times^* \tilde{R} + \tilde{R} \Omega_\times \\ &= [\tilde{R}, \Omega_\times^*] + \tilde{R}(\Omega_\times - \Omega_\times^*) \\ &= [\tilde{R}, \Omega_\times^*] + \tilde{R} \tilde{\Omega}_\times, \end{aligned} \quad (52.30)$$

where $[A, B] = AB - BA$ is the matrix commutator and

$$\tilde{\Omega} := \Omega - \Omega^*. \quad (52.31)$$

We assume that derivative $\dot{\Omega}^*$ of the target angular velocity is available for the purposes of designing a feedforward torque for the angular velocity dynamics

$$\tau^* := \mathbf{I} \dot{\Omega}^* + \Omega_\times^* \mathbf{I} \Omega^*, \quad (52.32)$$

where \mathbf{I} is the inertia matrix of the airframe (52.2d). Feed-forward control for the angular velocity of the attitude is important for high-performance maneuvers, especially when the motor response is pushed to near performance limits. The higher derivative information

for the angular velocity is available from path planning algorithms such as those discussed in Sect. 52.4.1 or using predictive control algorithms [52.8–10, 36]. Choose the control input

$$\tau := \tau^* + \mathbf{u}_2 \quad (52.33)$$

where $\mathbf{u}_2 \in \mathbb{R}^3$ is the free control that will be used to stabilize the error dynamics (Fig. 52.6). The error dynamics for the angular velocity error are now

$$\dot{\mathbf{I}}\tilde{\Omega} = -\tilde{\Omega}_\times \mathbf{I}\Omega + \mathbf{u}_2. \quad (52.34)$$

The goal is to choose \mathbf{u}_2 in order to stabilize the error dynamics (52.30) and (52.34) robustly. Define

$$\mathbb{P}(\tilde{R}) := \frac{1}{2}(\tilde{R} - \tilde{R}^T)$$

to be the skew-symmetric projection of the error matrix. It can be verified that $\mathbb{P}(\tilde{R}) = \sin(\theta)a_\times$ where (a, θ) is the angle-axis representation of \tilde{R} . That is the skew-symmetric projection is the axis of rotation that rotates R to R^* (equivalently rotates \tilde{R} to the identity) scaled by the sin of the angle between the two orientations. Choose a proportional–derivative (PD) control

$$\mathbf{u}_2 = -k_P \text{vex}(\mathbb{P}(\tilde{R})) - k_D \tilde{\Omega},$$

where $\text{vex}: \mathbb{R}^{3 \times 3} \rightarrow \mathbb{R}^3$ is the inverse of the skew-symmetric operator applied to skew-symmetric matrices, $\text{vex}(\Omega_\times) = \Omega$. The proportional term applies a torque associated with a nonlinear spring associated with a potential energy $\text{tr}(\tilde{R}^T \tilde{R})$ while the derivative $k_D \tilde{\Omega}$ provides damping. It is straightforward to demonstrate that the Lyapunov function

$$\mathcal{L} := k_P \text{tr}(\tilde{R}^T \tilde{R}) + \frac{1}{2} \tilde{\Omega}^T \mathbf{I} \tilde{\Omega}$$

is decreasing

$$\frac{d}{dt} \mathcal{L} := -k_D \|\tilde{\Omega}\|^2.$$

Invoking Barbalat's lemma, with some care, it follows that the system is almost globally asymptotically stable. The zero measure exception set for the basin of attraction is associated with situations where the quadrotor is completely flipped, $\theta = \pi$ rad, and $\mathbb{P}(\tilde{R}) = 0$ even though $\tilde{R} \neq I$.

To verify the local exponential convergence and provide guidance for the gain tuning, we consider the linearization of (52.30) and (52.34). Write $\tilde{R} \approx I + (z_R)_\times$ where the skew-symmetric matrix $(z_R)_\times$ (for $z_R \in$

\mathbb{R}^3) is the linear approximation of \tilde{R} around the identity matrix I . Write $\tilde{\Omega} \approx z_\Omega$ for the linear approximation of $\tilde{\Omega}$ around the origin $\tilde{\Omega} = 0$. The linearization of the error $z = (z_R, z_\Omega)$ system is given by

$$\begin{pmatrix} \dot{z}_R \\ \dot{z}_\Omega \end{pmatrix} = \begin{bmatrix} ((\Omega^*)_\times & 0 \\ 0 & \mathbf{I}^{-1}(\mathbf{I}\Omega)_\times \end{bmatrix} + \begin{pmatrix} 0 & 1 \\ -k_P \mathbf{I}^{-1} & -k_D \mathbf{I}^{-1} \end{pmatrix} \begin{pmatrix} z_R \\ z_\Omega \end{pmatrix} \quad (52.35)$$

or in more compact notation $\dot{z} = A(t)z$ where $A(t) = A_1(t) + A_2$ comprises the sum of two matrices in (52.35). The matrix $A_1(t)$ is a time-varying matrix depending on the exogenous system signals Ω and Ω^* while the second matrix A_2 is a time-invariant Hurwitz second-order linear system matrix. It is straightforward to show that this system is asymptotically stable using a Lyapunov function $\ell = k_P/2|z_R|^2 + 1/2z_\Omega^T \mathbf{I} z_\Omega$, using an analog of the nonlinear argument made earlier. We have that $\dot{\ell} = -k_D|z_\Omega|^2$. Define $C = \begin{pmatrix} 0 & I_3 \end{pmatrix} \in \mathbb{R}^{3 \times 6}$ then if the pair $(A(t), C)$ is uniformly completely observable (UCO) asymptotic stability implies exponential stability [52.37, pp. 626–628]. It is intuitively clear that the system matrices $(A(t), C)$ associated with (52.35) are UCO, although providing the algebraic proof is beyond the scope of this chapter. Tuning the gains is then a process of choosing k_P and k_D to assign the eigenvalues of the Hurwitz system matrix, with an eye to dominate the oscillatory, but bounded energy, disturbance introduced by $A_1(t)$.

Trajectory Tracking Control

The trajectory planning algorithm, discussed later in Sect. 52.4.1, provides a full trajectory specification as well as the feedforward inputs consisting of $(\xi^p, \dot{\xi}^p, R^p, \Omega^p, \dot{\Omega}^p, u_1^p, u_2^p)$ and their derivatives. The goal of trajectory tracking control is to regulate the linear dynamics of a quadrotor to track a specified goal trajectory $\xi^*(t)$. Trajectory tracking control operates at a higher level in the hierarchy of the quadrotor control architecture (Fig. 52.6) and the desired attitude R^* used in the attitude control loop is designed as an input in the trajectory loop control design. In addition to specifying the attitude goal, R^* , the trajectory tracking control specifies the heave (total thrust), T , input reference that is used along with (52.33) for the low-level motor control reference (52.9).

The linear trajectory goal $\xi^* = \xi^p$ and $\dot{\xi}^* = \dot{\xi}^p$ are used directly from the path planning design as the goal of the trajectory planner. The actuation for the linear dynamics, however, depends on the attitude of the vehicle. Thus, it is necessary to define the goal for the attitude control R^* as a part of the control design

rather than rely on the planned trajectory set-point; in particular $R^* \neq R^p$ in general. Note that the feedforward control in Sect. 52.3.1 requires Ω^* and $\dot{\Omega}^*$ to plan the feedforward torque input for the attitude dynamics. Feed-forward in the attitude regulation loop is a critical component of high-performance control and without this input, there will not be sufficient gain in the attitude dynamics to track aggressive attitude trajectories. However, computing the angular velocity goal that corresponds to a feedback dependent attitude control goal R^* in real-time requires forward prediction of the control trajectory using tools such as model predictive control (MPC) [52.8–10, 36]1. A simpler approach for trajectory tracking is to use the planned angular velocity $\Omega^* = \Omega^p$ even though it does not exactly match the variation of R^* . As long as $(\xi, \dot{\xi})$ is close to $(\xi^*, \dot{\xi}^*) = (\xi^p, \dot{\xi}^p)$ then R^* is close to R^p and $(\Omega^*, \dot{\Omega}^*) = (\Omega^p, \dot{\Omega}^p)$ will provide a good estimate of the critical feedforward attitude input.

We will discuss here the linear trajectory tracking algorithm for which the specified trajectory is required to have roll and pitch values that are small thus justifying a linear approximation of the dynamics. Accordingly, we assume that the Euler angles associated with the rotation R^p (52.1), are given by $\theta^p = \phi^p = 0$, while ψ^p is a specified function of t . For a given arbitrary yaw angle, we can linearize the dynamics about the hover position ($\theta = 0, \phi = 0, \psi = \psi^p$) and the nominal inputs $u_1 = mg, \mathbf{u}_2 = 0$. Linearizing (52.2a), we obtain

$$\begin{aligned}\ddot{\xi}_1 &= g(\Delta\theta \cos \psi^p + \Delta\phi \sin \psi^p), \\ \ddot{\xi}_2 &= g(\Delta\theta \sin \psi^p - \Delta\phi \cos \psi^p), \\ \ddot{\xi}_3 &= \frac{1}{m}u_1 - g,\end{aligned}\quad (52.36)$$

where $\Delta\theta = \theta^*$ and $\Delta\phi = \phi^*$ represent the small deviations from the hover position. In order to exponentially drive all three components of error in the position part of the trajectory, we want the acceleration vector $\ddot{\xi}$ to satisfy

$$(\ddot{\xi}^* - \ddot{\xi}) + K_d(\dot{\xi}^* - \dot{\xi}) + K_p(\xi^* - \xi) = 0.$$

From (52.36), we can immediately write

$$u_1 = m \left[g + \ddot{\xi}_3^* + k_{d,z}(\dot{\xi}_3^* - \dot{\xi}_3) + k_{p,z}(\xi_3^* - \xi_3) \right], \quad (52.37)$$

to guarantee $(\xi_3(t) - \xi_3^*(t)) \rightarrow 0$. We choose the appropriate desired roll, pitch, and yaw angles for $\theta^*, \phi^*,$

and ψ^* to guarantee exponential convergence:

$$\phi^* = \frac{1}{g}(\ddot{\xi}_1^* \sin \psi - \ddot{\xi}_2^* \cos \psi), \quad (52.38a)$$

$$\theta^* = \frac{1}{g}(\ddot{\xi}_1^* \cos \psi + \ddot{\xi}_2^* \sin \psi), \quad (52.38b)$$

$$\psi^* = \psi^p. \quad (52.38c)$$

Now $(\psi^*, \phi^*, \theta^*)$ define the rotation matrix R^* (52.1) provided as a set point for the exponentially convergent attitude controller discussed in the previous section. Thus, as shown in Fig. 52.6, the control problem is addressed by decoupling the position control and attitude control subproblems and the position control loop provides the attitude set points for the attitude controller.

The position controller can also be obtained without linearization. This is done by projecting the position error (and its derivatives) along \mathbf{b}_3 and applying the input u_1 that cancels the gravitational force and provides the appropriate proportional plus derivative feedback

$$u_1 = m\mathbf{b}_3^T \left[\ddot{\xi}^* + K_d(\dot{\xi}^* - \dot{\xi}) + K_p(\xi^* - \xi) + g\mathbf{e}_3 \right]. \quad (52.39)$$

Note that the projection operation is a nonlinear function of the roll and pitch angles and thus this is a nonlinear controller. In [52.7, 35], it is shown that this approach results in exponential stability and allows the robot to track trajectories in SE(3).

52.3.2 Control of Fixed-Wing Aircraft

An aircraft is a highly coupled nonlinear dynamical system and it may seem most natural to treat the control problem as an integrated multi-input multi-output (MIMO) nonlinear design [52.29, 38–40]. However, despite the nonlinear coupling of aircraft states there are still clear dependencies between specific actuators and certain dynamic modes of the open-loop response. A disadvantage of the MIMO approach is that it tends to obscure insight between control design and specific open-loop mode response. Moreover, and as a consequence, it tends to be less robust to large changes in model parameters (such as caused by using a different set of wings, or bolting on a completely new sensor package, not an uncommon situation for a small UAV system) than a classical control design. The classical, and more intuitive, control architecture for fixed wing vehicles is to consider a set of separate, but interconnected, single-input single-output (SISO) control loops. Such an approach has the advantage of being highly intuitive and leading to a modular design methodology

based on successive loop closure, providing a straight-forward gain tuning regime [52.31]. The robustness and simplicity of the **SISO** architecture make it the preferred choice for most small **UAV** control systems. A modern implementation, however, uses the total energy control system (**TECS**) architecture and input decoupling to overcome some of the limitations of classical fixed-wing control design.

The main control actions for a fixed wing aircraft are associated with the throttle, and the three aerodynamic control surfaces; rudder, ailerons, and elevators. The throttle regulates power to the motor and governs thrust T . The rudder, ailerons and elevators actuate the angular velocities Ω_z , Ω_x , and Ω_y , respectively, through the angular dynamics of the vehicle. For a small fixed-wing **UAV** in normal flight, a simple high-gain proportional control scheme will effectively regulate and decouple the variables $(T, \Omega_x, \Omega_y, \Omega_z)$ [52.31]. The control problem can then be posed as one where $(T, \Omega_x, \Omega_y, \Omega_z)$ are inputs for regulation of the remainder of the vehicle dynamics. Since there is weak physical coupling between the lateral variables (roll rate, bank angle, yaw rate, and course angle) and the longitudinal variables (airspeed, pitch rate, pitch angle, altitude rate, and altitude), and since the elevator and rudder most strongly effect the lateral variables and the throttle and aileron most strongly influence the longitudinal variables, most control architectures separate functionality into a lateral control system and a longitudinal control system. The input to the lateral control system is the desired course angle, and the input to the longitudinal control system is the desired airspeed and the desired altitude.

Lateral Control System

There are three open-loop dynamic modes associated with the response of the lateral dynamics of a fixed-wing aircraft: the roll mode, the spiral mode, and the dutch roll mode. The *roll mode* is associated with the first-order response of the roll rate of the vehicle to aileron input. Usually the wings and airframe are designed (e.g., with a positive dihedral angle Chap. 26.4.4) so that this mode is highly stable and is regulated using high-gain in the aileron input – indeed, this mode is subsumed into the control simplification (regulation of Ω_z) proposed above.

The spiral mode is associated with the natural turning motion of the vehicle. That is, if the vehicle is banked into a turn, it will continue to turn until control action is applied to flatten the vehicle out. The spiral mode is a linearization of the bank-to-turn dynamics and is a single real pole close to the origin (Chap. 26, Fig. 26.22). Typically the spiral mode is slightly unstable due to the tendency of the vehicle to side-slip

into a turn. In manned flight, the spiral mode can be dangerous since there is very little external perception of turning. The nature of the banked turn dynamics ensure that the body-fixed-frame acceleration remains oriented through the central axis of the vehicle and rate of rotation is slow and nearly constant. The mode becomes dangerous if the pilot is not aware as the vehicle slowly side-slips down into the turn, progressively diving more and more steeply and increasing airspeed in what is known as a *spiral-dive*. For autonomous flight control, the spiral mode is relatively benign since autopilots never stop looking at the instruments and take immediate action if the vehicle is drifting off course.

The *dutch-roll* mode, is associated with the oscillation of the vehicle around a heading. In this motion, the vehicle yaws away from the heading and then rolls due to the dihedral effect, before the tilted lift vector and rudder action force the airplane back toward the incident wind. If the rudder is small and does not provide sufficient damping, the vehicle can overshoot to yaw and roll in the other orientation before repeating the oscillatory sequence. Dutch roll motion is less dangerous for manned flight since it is usually stable (except for vehicles with strongly swept back wings or negative dihedral) and produces unpleasant sideways acceleration with the side-slip motion that is immediately apparent to a pilot. Damping is increased by large tail plane surfaces and moderate to small dihedral. A figure of the typical pole positions of an aerobatic RC airplane is shown in Chap. 26, Fig. 26.22.

To understand the control problem for lateral dynamics, consider first the angular yaw velocity Ω_z induced by rudder actuation. The primary effect of Ω_z will yaw the vehicle in the air and generate nonzero side-slip β . In the *bank-to-turn* control paradigm described later, we will use Ω_z to regulate $\beta \equiv 0$, however, it is instructive first to consider the effect of nonzero side-slip in order to build an intuitive understanding of the lateral dynamics. If the side-slip $\beta \neq 0$, the airplane will be sliding sideways or crabbing through the air. In particular, applying rudder input (nonzero Ω_z) acts to twist the airplane in the air; it does not in itself cause the trajectory of the airplane to curve. For a typical airplane with dihedral, this will lead the aircraft to bank away from the side-slip, and if the dutch-roll mode is stable, the airplane will settle into a banked turn. The causality of the system signals is given by

$$\Omega_z \rightarrow \beta \rightarrow \phi \rightarrow \chi.$$

Here the actuation from $\beta \rightarrow \phi$ relies on the inherent stability of the dutch roll mode of the lateral open-loop dynamics of the airframe. Indeed, small-scale vehicles with strong dihedral and large tail planes can be flown

without aileron surfaces. For example, the aerial robotic vehicle as shown in Fig. 52.7, designed for slow low-level flight and equipped for visual terrain tracking using optic flow computed from a pair of downward pointing web cameras [52.41], does not have ailerons and the lateral motion is controlled using only the rudder.

This control paradigm has several negatives. It is rarely used for manned flight because side-slip motion generates sideways accelerations that do not feel natural. More importantly, the control response is limited by the low pass response of the open loop dutch roll dynamics of the aircraft. Although this mode is stable, there is often a noticeable damped oscillatory response that causes the vehicle trajectory to wander around the desired heading and degrades course tracking performance.

The alternative is to explicitly use the ailerons to impose the desired roll angle ϕ on the vehicle and actuate the heading dynamics (52.27a) without using the rudder. The rudder then becomes a separate control input that can be used to regulate β . That is

$$\begin{aligned}\Omega_z &\rightarrow \beta, \\ \Omega_x &\rightarrow \phi \rightarrow \chi.\end{aligned}$$

Although, this may seem counter intuitive, (the rudder is not used to steer the airplane) it is, however, the most effective heading control strategy. Using this control strategy and regulating the side-slip $\beta \equiv 0$ ensures that the bank-to-turn simplifications can be applied to the model as was shown in Sect. 52.2.3.

Specifically, in the bank-to-turn strategy where side-slip β is regulated to zero using the rudder, the lateral equations of motion are given by (52.24) and (52.27a). In level flight where the pitch angle is small and the velocity and angle of attack are roughly a constant, these

Fig. 52.7 An autonomous fixed-wing aerial robot for experimental work on vision-based terrain tracking at ANU (after [52.41]). Note the upswept wings to generate dihedral and the lack of ailerons

equations simplify to the cascade structure

$$\begin{aligned}\dot{\phi} &= \Omega_x + d_\phi, \\ \dot{\chi} &= -A_\chi \phi + d_\chi,\end{aligned}$$

where A_χ is a constant and d_ϕ and d_χ are disturbance signals introduced through the modeling process. From classical control theory, we know that a step in the heading command χ^* can be tracked while simultaneously rejecting low-frequency disturbances d_ϕ and d_χ using a nested PI control law given by

$$\phi^* = k_{p_\chi}(\chi^* - \chi) + k_{I_\chi} \int_{-\infty}^t (\chi^* - \chi) d\tau, \quad (52.40)$$

$$\Omega_x = k_{p_\phi}(\phi^* - \phi) + k_{I_\phi} \int_{-\infty}^t (\phi^* - \phi) d\tau, \quad (52.41)$$

where k_{p_χ} , k_{I_χ} , k_{p_ϕ} , and k_{I_ϕ} are positive control gains. The proportional control

$$\Omega_z = -k_{p_\beta} \beta, \quad (52.42)$$

is usually effective at regulating the side-slip angle to zero, where k_{p_β} is a positive control gain.

Longitudinal Control System

The longitudinal dynamics concern the thrust T and elevator (regulating Ω_y) inputs, along with the angle of attack α , the flight path angle γ , the airspeed $|v_a|$, and the altitude h . There are two primary open-loop dynamic modes associated with the open loop response of the longitudinal dynamics, the short-period and phugoid modes. The *short-period* mode is associated with variation of pitch of the vehicle for constant velocity, constant altitude flight. It is a consequence of the linear dependence of lift of the primary wing to angle-of-attack as the vehicle pitches up and down around its center of the mass. The center of mass of an airplane is always designed to lie in front of the center of force of the primary wing surface to ensure that the short-period mode oscillation is stable, (placing the mass further forward increases the stability margin,) while damping provided by the tail plane of the vehicle ensures asymptotic stability (Chap. 26.4.2).

The *phugoid mode* is associated with the interplay of aerodynamic lift, velocity, glide path, and height of the vehicle for constant angle-of-attack flight. As a vehicle starts to descend gently, the airspeed increases as the loss of potential energy in height is transferred into kinetic energy. As the vehicle accelerates, the increased airspeed leads to increased primary lift on the wings leading the vehicle to pull out of the dive and to start to ascend again. The vehicle will slow as the

stored kinetic energy is traded back into potential energy. The resulting open-loop unstabilized motion is a repeated swooping cycle. Since aircraft are designed with low drag coefficients, the phugoid mode is usually very lightly damped, however, it is slow and easily stabilized. A key point to note in phugoid motion is that it is a constant energy oscillation; potential energy is transformed into kinetic energy and is then transformed back into potential energy.

Both thrust and pitch rate inputs affect both velocity and angle-of-attack of an airplane. In turn, the glide-path angle can be controlled through regulation of either angle-of-attack or velocity of the vehicle. The coupling associated with these dependencies mean that simple thrust to velocity or pitch-rate to glide-path SISO control loops cannot cover the full flight regime of a typical aircraft, a limitation of many existing autopilot systems even in commercial airliners. The industry standard approach to address this issue is to have different control modes for different flight conditions, take-off and climb, level flight, and descent, that exploit different input to state control mappings [52.31]. The total energy control system (TECS) design paradigm [52.42, 43] partially avoids these difficulties for a wide range of operating conditions and has the additional advantage of minimizing the control activity undertaken by the throttle.

Due to the energy preserving nature of the phugoid mode, small variations in velocity and height tend to be stable and energy conserving. Based on this insight, it is desirable to allow small variations of the airspeed of the vehicle as long as it is associated with the phugoid mode response. The key characteristic of the phugoid mode is that it preserve *total energy*

$$E := \frac{1}{2}m|v_a|^2 + mgh \quad (52.43)$$

of the aircraft. The TECS control architecture uses the total energy as an output and uses the throttle to regulate this output to a desired energy set point. The set point

$$E^*(t) := \frac{1}{2}m|v_a^*|^2 + mgh^*$$

is chosen to correspond to the desired trajectory. The energy error is

$$\tilde{E} := E^*(t) - E(t),$$

and the throttle input is assigned as

$$\delta_t = k_{p_E}\tilde{E}(t) + k_{i_E}\int_{-\infty}^t \tilde{E}(\tau) d\tau, \quad (52.44)$$

where k_{p_E} and k_{i_E} are positive control gains.

Once the throttle input is assigned, the remaining longitudinal dynamics must be controlled using the elevator to servo the pitch rate Ω_y . The primary effect

of pitch rate is to rotate the wing section of the aircraft, directly effecting the angle-of-attack. Changing the angle-of-attack effects lift and drag generated by the wing, with lift most strongly effected since it depends linearly on α (52.14) while drag is small and only varies with the square of the angle-of-attack (52.15). By definition, the lift L is the component of airfoil force that lies perpendicular to the velocity. As a consequence the lift force L does not contribute directly to changes in the total energy E of the vehicle. In particular, actuation of the pitch dynamics of the vehicle is (almost) decoupled from total energy regulation loop. It is now possible to choose an output for the elevator input and have confidence that the resulting SISO loop response will only marginally disturb the total energy regulation loop. Rather than simply regulate the height or velocity, both variables that have been considered as outputs for elevator regulation loops in classical fixed-wing control architectures [52.31], it is of interest to regulate a balance between kinetic and potential energy [52.42].

Consider the kinetic energy and potential energy of the vehicle separately

$$K = \frac{1}{2}m|v_a|^2, \quad U := mgh.$$

A given flight trajectory corresponding to desired values of $(|v_a^*(t)|, h^*(t))$ defines desired set points for kinetic and potential energy $K^*(t) = \frac{1}{2}m|v_a^*(t)|^2$ and $U^* = mgh^*(t)$. Define the errors in the kinetic and potential energy along the trajectory as

$$\begin{aligned} \tilde{K} &= K^*(t) - K(t) = \frac{1}{2}m[|v_a^*(t)|^2 - |v_a(t)|^2], \\ \tilde{U} &= U^*(t) - U(t) = mg[h^*(t) - h(t)], \end{aligned} \quad (52.45)$$

and define the combined energy balance error \tilde{B} by

$$\tilde{B} = \tilde{K} - \tilde{U}.$$

The proposed control strategy is to use the commanded pitch angle θ^* to regulate $\tilde{B} \rightarrow 0$.

To understand this control architecture, note that if $\tilde{E} = 0$ then $\tilde{K} = \tilde{E} - \tilde{U} = -\tilde{U}$ and hence

$$\tilde{B} = 2\tilde{K} = -2\tilde{U}.$$

It follows that driving \tilde{B} to zero forces both $|v_a| \rightarrow |v_a^*|$ and $h \rightarrow h^*$. The real advantage of the balanced energy control architecture occurs when $\tilde{E} \neq 0$. In this case, driving $\tilde{B} \rightarrow 0$ will not force either $|v_a|$ or h to its reference set point at all costs, but rather, it will balance the excess or deficit energy between kinetic and potential energy set points around the desired trajectory.

Balancing the energy error in this way is a highly robust control strategy that maximizes the ability of the throttle to maintain good control of the total energy.

An additional insight is that the difference of the energy terms \tilde{B} is maximally sensitive to excitation in the phugoid mode. In particular, if power flows between potential and kinetic energy levels, then the relative variation in \tilde{B} is maximal compared to any other combined measure incorporating $|v_a|$ and h subject to scaling factors. Thus, the balanced energy control strongly directly damps the phugoid mode that is uncontrolled by the thrust control.

The desired pitch angle is therefore given by

$$\theta^* = k_{p_B} \tilde{B}(t) + k_{I_B} \int_{-\infty}^t \tilde{B}(\tau) d\tau, \quad (52.46)$$

where k_{p_B} and k_{I_B} are positive control gains. In practice, the pitch angle actuates stable angle-of-attack dynamics that in turn lead to regulation of the flight-path angle and finally control the tradeoff encoded in \tilde{B} . The stability of the internal dynamics for the proposed SISO control loop are handled by suitable tuning of the PI gains, avoiding the need to explicitly model these dynamics. The effectiveness and robustness of this approach is well established in the literature [52.31].

Control Implementation and Gain Tuning

The lateral control strategy for fixed wing aircraft is based on (52.40), (52.41), and (52.42). In using these commands, we are assuming high-bandwidth feedback loops regulating Ω_x and Ω_z using the ailerons and rudder, respectively. Practical implementation of the lateral control loops required saturating the roll command ϕ^* to $\pm\bar{\phi}$, where, for most airframes, a reasonable value is $\bar{\phi} = 30^\circ$. Commanding higher roll angles usually results in large side-slip angles, which leads to unacceptably large drops in altitude during turns. The roll rate command Ω_x is also saturated to a fraction of the limits of the rate gyro sensor to ensure adequate convergence of the attitude estimator. Practical implementation of (52.40) also requires careful wrapping of the angles χ and χ^* around $\pm 180^\circ$ to avoid large heading errors that result in not associating 180° with -180° .

The gains of the lateral control loops can be tuned in flight by selectively enabling one loop at a time. A strategy that has proven success over numerous flight test is to tune the gains in the following order:

1. Attitude rate loops regulating Ω_x and Ω_z .
2. Side slip gain k_{p_β} .
3. The proportional gain on roll error k_{p_ϕ} , followed by the integral gain k_{I_ϕ} . The integral gain k_{I_ϕ} is often

set to zero, since the integrator on the heading loop provides suitable robustness.

4. The proportional gain on the heading loop k_{p_χ} , followed by the integral gain k_{I_χ} .

The use of (52.46) assumes a high-bandwidth pitch control loop using the elevator as an actuator. Practical implementation of (52.44) requires saturating δ_i above by δ_i^{\max} and below by $\delta_i^{\min} \geq 0$. Saturating the pitch angle is also critical to avoid stall conditions that occur at large angles of attack. An effective method to do this is to saturate the altitude error in computing the error in potential energy, replacing (52.45) with

$$\tilde{U} = mg \text{sat}[h^*(t) - h(t), \bar{h}], \quad (52.47)$$

where

$$\text{sat}(x, \ell) = \begin{cases} \ell & \text{if } x \geq \ell, \\ -\ell & \text{if } x \leq -\ell, \\ x & \text{otherwise.} \end{cases}$$

Saturating the altitude error will cause a steady climb rate when $h^* - h$ is large. To understand why, assume that velocity is well regulated, and that the altitude error is large, then $\tilde{B} \approx -mg \text{sat}(h^* - h, \bar{h}) = -mg\bar{h}$. Ignoring the integrator, this will cause a constant pitch angle command from (52.46). However, simply saturating the pitch angle will not result in good performance since driving

$$\begin{aligned} \tilde{B} = \tilde{K} - \tilde{U} = & \frac{1}{2}m(|v_a^*(t)|^2 - |v_a(t)|^2) \\ & - mg[h^*(t) - h(t)] \end{aligned}$$

to zero will cause errors in kinetic and potential energy to balance. Therefore, a large unsaturated altitude error will result in the controller increasing the airspeed error. A sustained altitude error will cause the integrator in (52.46) to wind up. Therefore, an integrator antiwindup scheme is essential.

Similar to the lateral control loop, the gains for the longitudinal controller can be tuned in flight by selectively enabling one loop at a time. The gains should be tuned in the following order:

1. The pitch attitude loops is first tuned. Pitch attitude is typically controlled using a PID controller. The derivative gain can be tuned to provide adequate damping on the RC controller. The proportional gain is then added and adjusted to provide adequate transient response. The integrator is added afterward to remove steady state error in pitch.
2. The throttle gains k_{p_E} and k_{I_E} in (52.44) are then adjusted. We have found that normalizing the energy error \tilde{E} by the reference kinetic energy $K^{\text{ref}} = \frac{1}{2}m|v_a^{\text{ref}}|$ makes these gains particularly easy to tune,

and that the scaling results in similar gains working across different platforms.

3. The energy balance gains k_{p_B} and k_{l_B} are tuned last. Again, scaling \tilde{B} by K^{ref} seems to simplify the tuning process for different airframes.

An advantage of the **TECS** is that it reduces the need for different control modes for the longitudinal autopilot. In particular, the *altitude hold mode*, the *climb mode*, and the *descend mode* described in [52.31] are reduced to one mode using **TECS**. However, we should

note that the *take-off mode* described in [52.31] is still needed for this scheme. For small aircraft that are hand launched, or any aircraft whose velocity at take off is significantly below the commanded velocity, the **TECS** control in (52.46) will cause the vehicle to pitch down to gain airspeed when the airspeed error is large. This pitch-down behavior will cause the airframe to crash if it is executed immediately after take-off. Therefore, the best strategy is to apply full throttle immediately after take-off, and to set the commanded pitch angle to fixed value that is adequate for a climb rate that avoids stall.

52.4 Trajectory Planning

There are many different control tasks that aerial robotic vehicles will be required to undertake in the coming years. In this chapter, it is impossible to cover the whole range of potential tasks along with their associated planning problems. We will consider only basic trajectory or path planning problems for both quadrotor and fixed-wing vehicles. This problem is fundamental to fixed-wing navigation where the distances involved are such that path and trajectory planning is sufficient for almost all goals. For small aerial robotic vehicles flying in cluttered 3-D-spaces, there is a much wider selection of goals including things such as, physical interaction with the environment, obstacle avoidance, etc., as well as simply planning and following a trajectory to a given way-point. However, the trajectory planning provides a basic building block in achieving a wide range of goals, and is a necessary component of achieving high-performance tasks.

52.4.1 Trajectory Planning for Quadrotors

The quadrotor is underactuated and this makes it difficult to plan trajectories in 12-dimensional state space (6DOF position and velocity). However, the problem is considerably simplified if we use the fact that the quadrotor dynamics are differentially flat [52.44]. To see this, we consider the output position ξ and the yaw angle ψ . We show that we can write all state variables and inputs as functions of the outputs (ξ, ψ) and their derivatives. Derivatives of ξ yield the velocity v , and the acceleration,

$$\dot{v} = \frac{1}{m} u_1 \mathbf{b}_3 + g \mathbf{e}_3.$$

From Fig. 52.3, we see that

$$\mathbf{d}_1 = [\cos \psi, \sin \psi, 0]^T$$

and the unit vectors for the body-fixed frame, can be written in terms of the variables ψ and $\dot{\psi}$ as follows

$$\mathbf{b}_3 = \frac{\dot{\psi} - g \mathbf{e}_3}{\|\dot{\psi} - g \mathbf{e}_3\|}, \mathbf{b}_2 = \frac{\mathbf{b}_3 \times \mathbf{d}_1}{\|\mathbf{b}_3 \times \mathbf{d}_1\|}, \mathbf{b}_1 = \mathbf{b}_2 \times \mathbf{b}_3$$

provided $\mathbf{b}_3 \times \mathbf{d}_1 \neq 0$. This defines the rotation matrix ${}^A R_B$ as a function of $\dot{\psi}$ (the second derivative of ξ) and ψ . In this way, we write the angular velocity and the four inputs as functions of the position, velocity ($v = \dot{\xi}$), acceleration ($a = \ddot{\xi}$), jerk ($\gamma = \xi^{(iii)}$), and snap or the derivative of jerk ($\sigma = \xi^{(iv)}$). From these equations, it is possible to verify that there is a diffeomorphism between the 18×1 vector

$$\mathbf{X} = (\xi^T, v^T, a^T, \gamma^T, \sigma^T, \psi^T, \dot{\psi}^T, \ddot{\psi}^T)^T$$

and the state augmented with the inputs and their derivatives

$$(\xi^T, \dot{\xi}^T, R, \Omega^T, u_1, \dot{u}_1, \ddot{u}_1, \mathbf{u}_2^T)^T.$$

This property of differential flatness makes it easy to design trajectories that respect the dynamics of the underactuated system. Any four-times-differentiable trajectory in the space of flat outputs, $(\xi^T(t), \psi(t))^T$, corresponds to a feasible trajectory, one that satisfies the equations of motion. All inequality constraints of states and inputs can be expressed as functions of the flat outputs and their derivatives. This mapping to the space of flat outputs can be used to generate trajectories that minimize a cost functional formed by a weighted combination of the different flat outputs and

then the Dubins car path must be suitably modified. One alternative is to fly at the flight path angle constraint while making multiple complete orbits on the minimum turn radius helix at the beginning of the Dubins car path before proceeding along the straight line segment of the path. Of course, a similar strategy would be to make multiple complete orbits on the minimum turn radius helix at the end of the Dubins car path. Such paths are termed *high-altitude paths* in [52.51]. The middle case is when the flight path angle constraint does not allow sufficient altitude gain/loss following the Dubins car path, but where one complete orbit along the start or end circle of the Dubins car path at the maximum flight path angle results in more altitude gain/loss than is needed. In this case, a deviation can be placed in the Dubins car path to extend the path length to just the right amount so that the altitude gain/loss can be achieved while flying at the flight path angle constraint. These paths are termed *medium-altitude paths* in [52.51].

Following the notation defined in [52.52] let $L_{\text{car}}(C_s, C_e, R)$ denote the path length of the Dubins car path between the projection of the start configuration C_s onto the North–West plane, and the projection of the end configuration C_e onto the North–West plane, using R as the turn radius of the vehicle.

Low-Altitude Dubins Paths

The altitude gain between the start and end configuration is said to be *low altitude* if

$$|h_e - h_s| \leq L_{\text{car}}(C_s, C_e, R_{\min}) \tan \bar{\gamma},$$

where the term on the right is the maximum altitude gain that can be obtained by flying at flight-path angle $\pm \bar{\gamma}$ for a distance of $L_{\text{car}}(C_s, C_e, R_{\min})$.

In the low-altitude case, the altitude gain between the start and end configurations can be achieved by flying the Dubins car path with a flight-path angle satisfying $|u_2| \leq \bar{\gamma}$. Therefore, the optimal flight-path angle can be computed by

$$u_2^* = \tan^{-1} \left(\frac{|h_e - h_s|}{L_{\text{car}}(C_s, C_e, R_{\min})} \right).$$

Medium-Altitude Dubins Paths

The altitude gain between the start and the end configuration is said to be *medium altitude* if

$$\begin{aligned} L_{\text{car}}(C_s, C_e, R_{\min}) \tan \bar{\gamma} &< |h_e - h_s| \\ &\leq [L_{\text{car}}(C_s, C_e, R_{\min}) + 2\pi R_{\min}] \tan \bar{\gamma}, \end{aligned} \quad (52.49)$$

where the addition of the term $2\pi R_{\min}$ accounts for adding one orbit at radius R_{\min} to the path length.

In the medium-altitude case, the altitude difference between the start and end configurations is too large to

obtain by flying the Dubins car path at the flight-path angle constraint, but small enough that adding a full turn on the helix at the beginning or end of the path and flying so that $\gamma = \pm \bar{\gamma}$ results in more altitude gain/loss than is needed. As shown in [52.51], the minimum distance path is achieved by setting $\gamma = \text{sign}(h_e - h_s) \bar{\gamma}$ and inserting an extra maneuver in the Dubins car path that extends the path length so that the altitude gain when $\gamma = \pm \bar{\gamma}$ is exactly $|h_e - h_s|$. While there are numerous possible ways to extend the path length, the method proposed in [52.52] is to add an additional intermediate arc to the start or end of the path, as shown in Figs. 52.8 and 52.9. If the start altitude is lower than the end altitude, then the intermediate arc is inserted immediately after the start helix. If on the other hand, the start altitude is higher than the end altitude, then the intermediate arc is inserted immediately before the end helix.

High-Altitude Dubins Paths

The altitude gain between the start and end configurations is said to be *high altitude* if

$$|h_e - h_s| > [L_{\text{car}}(C_s, C_e, R_{\min}) + 2\pi R_{\min}] \tan \bar{\gamma}.$$

In the high-altitude case, the altitude gain cannot be achieved by flying the Dubins car path within the flight-path angle constraints. As shown in [52.51], the minimum distance path is achieved when the flight-path angle is set at its limit of $\pm \bar{\gamma}$, and the Dubins car path is extended to facilitate the altitude gain. While there are many different ways to extend the Dubins car path, [52.52] suggests extending the path by spiraling a certain number of turns at the beginning or end of the path, and then by increasing the turn radius by the appropriate amount.

For UAV scenarios, the most judicious strategy is typically to spend most of the trajectory at as high an altitude as possible. Therefore, if the altitude at the end configuration is higher than the altitude at the start configuration, then the path will be extended by a climbing helix at the beginning of the path. If on the other hand, the altitude at the start configuration is higher than the end configuration, then the path will be extended by a descending helix at the end of the path. If multiple turns around the helix are required, then the turns could be split between the start and end helices and still result in the same path length. For high-altitude Dubins paths, the required number of turns in the helix will be the smallest integer k such that

$$\begin{aligned} [L_{\text{car}}(C_s, C_e, R_{\min}) + 2\pi k R_{\min}] \tan \bar{\gamma} &\leq |h_e - h_s| \\ &< [L_{\text{car}}(C_s, C_e, R_{\min}) + 2\pi(k+1)R_{\min}] \tan \bar{\gamma}, \end{aligned} \quad (52.50)$$

Fig. 52.8 A top down view of low altitude, medium altitude, and high-altitude Durbin airplane paths. The initial and end configurations are identical except for the final altitude

or in other words

$$k = \left\lfloor \frac{1}{2\pi R_{\min}} \left[\frac{|h_e - h_s|}{\tan \bar{\gamma}} - L_{\text{car}}(C_s, C_e, R_{\min}) \right] \right\rfloor,$$

where $\lfloor x \rfloor$ is the floor function that rounds x down to the nearest integer. The radius of the start and end helices is then increased to R^* so that

$$\left[L_{\text{car}}(C_s, C_e, R^*) + 2\pi k R^* \right] \tan \bar{\gamma} = |h_e - h_s|. \quad (52.51)$$

Figures 52.8 and 52.9 show two perspective of three different Dubins airplane paths that start and end in the same configuration with the exception of the final altitude, which changes from 250 m for the low-altitude path, to 350 m for the medium-altitude path, to 450 m for the high-altitude path. A top down view is shown in Fig. 52.8. Note that for both the low-altitude and medium-altitude paths, that the minimum turn radius constraint is active, whereas for the high-altitude path, the turn radius in the turns is larger than the minimum turn radius constraint. A three-dimensional view

Fig. 52.9 A three-dimensional view of low altitude, medium altitude, and high-altitude Durbin airplane paths. The initial and end configurations are identical except for the final altitude

is shown in Fig. 52.9. Note that for both the medium- and high-altitude paths, the flight path angle constraint is active, but that it is not active for low-altitude paths.

There are a variety of techniques that allow the control architecture described in Sect. 52.3.2 to follow Dubins airplane paths. A simple method is to parameterize the path using a path parameter σ . Suppose that the resulting parameterized path is given by $p(\sigma)$. At each sample time, the path parameter is advanced along the path so as to minimize the distance to the path from the aircraft

$$\sigma_{t+1} = \arg \min_{s \geq \sigma_t} \|\xi(t) - p(s)\|,$$

where $\xi(t)$ is the inertial position of the aircraft. The commanded airspeed $|v_a^*|$, course angle χ^* , and altitude h^* at time t are then given by the parameterized Dubins airplane path $p(\sigma_{t+1})$. This technique is similar to the guidance strategy suggested in [52.53]. Alternative method based on vector field methods are described in [52.54–56].

52.5 Estimating the Vehicle State

A critical aspect in implementation of real world aerial robotic vehicles is providing good estimates of the state of the vehicle. The key state estimates required for control of an aerial vehicle are associated with the rigid-body dynamics of its airframe, height, attitude, angular velocity, and linear velocity. Moreover, fixed-wing vehicle dynamics depend on the aerodynamics states of angle-of-attack and side-slip angle. Of these states, the attitude and angular velocity are the most important as they are the primary variable used in attitude control and flight-regulation of the vehicle. Angle-of-attack and side-slip angles are rarely estimated explicitly and are dealt with as internal dynamics in the control design rather than explicit outputs or disturbances.

The ubiquitous instrumentation carried by any aerial vehicle is an inertial measurement unit (IMU) often augmented by some form of height measurement, either acoustic, infra red, barometric, or laser based. Vehicles that fly in outside environments carry a GPS system, most of which now provide velocity estimation as well as position. Many fixed wing vehicles also include a pitot tube (for dynamic pressure) or an anemometer to measure forward velocity. Indoor aerial robotic vehicles in research laboratories are often flown in flight environments equipped with motion capture systems like VICON or Optitrack [52.5, 6]. Finally, many aerial robotic systems have also been equipped with exteroceptive sensor systems including Kinect 3D-range cameras, scanning laser rangefinder, integrated stereo camera systems, or simple monocular cameras. There is an active research field in developing 3-D-SLAM (simultaneous localization and mapping; Chap. 46.4) algorithms for mapping and localization of aerial robotic vehicles.

The rigid-body dynamic state is crucial to the control performance of an aerial robotic system and we will concentrate on this estimation problem in this chapter. A natural approach to state-estimation is to apply classical filter design to a coordinate representation of the rigid-body state. A good development of this approach for small-scale aerial robotic systems is presented in [52.31]. An alternative approach is to exploit the nonlinear structure of the rigid-body kinematics to develop nonlinear observers. This approach has been shown to generate simple, robust, and highly effective filters for small-scale aerial robotic systems, especially for the key problem of attitude estimation.

52.5.1 Estimating Attitude

A typical IMU includes a three-axis rate gyro, three-axis accelerometer, and three-axis magnetometer. The

rate gyro measures angular velocity of $\{B\}$ relative to $\{A\}$ expressed in the body-fixed-frame of reference $\{B\}$

$$\Omega_{\text{IMU}} = \Omega + b_{\Omega} + \eta \in \{B\},$$

where η denotes additive measurement noise and b_{Ω} denotes a constant (or slowly time-varying) gyro bias. Generally, the gyroscopes installed on quadrotor vehicles are lightweight MEMS devices that are reasonably robust to noise and quite reliable.

The accelerometers (in a strap down IMU configuration) measure the instantaneous linear acceleration of $\{B\}$ due to exogenous force

$$a_{\text{IMU}} = R^T(\dot{v} + ge_3) + b_a + \eta_a \in \{B\}, \quad (52.52)$$

where b_a is a bias term, η_a denotes additive measurement noise, and \dot{v} is in the inertial frame. Accelerometers are highly susceptible to vibration and mounted on a typical aerial robotic platform they require significant low-pass mechanical and/or electrical filtering to be reliable. Most vehicles avionics will incorporate an analogue anti-aliasing filter on a MEMS accelerometer before the signal is sampled.

The magnetometers provide measurements of the ambient magnetic field

$$m_{\text{IMU}} = R^T {}^A m + B_m + \eta_b \in \{B\},$$

where ${}^A m$ is the Earth's magnetic field vector (expressed in the inertial frame), B_m is a body-fixed-frame expression for the local magnetic disturbance and η_b denotes measurement noise. The noise η_b is usually quite low for magnetometer readings, however, the local magnetic disturbance B_m can be very significant, especially if the sensor is placed near power cables for the motors.

In outdoor environments, the GPS is typically used to provide position, inertial velocity, and course angle. The GPS system consists of a constellation of 24 satellites that continuously orbit the earth at an altitude of 20 180 km. The position of a GPS receiver is determined by observing the time-of-flight of signals sent from the satellites and detected by the receiver. If accurate timing information is available at the receiver, then a minimum of three satellites signals are necessary to resolve the position of the receiver. However, for low-cost GPS receivers, timing information must also be received and this requires a minimum of four satellite signals. A variety of factors effect the accuracy of GPS estimates. The dominant sources of error include inaccurate satellite orbital data, inaccuracy in the satellite clocks, variable signal delay as it passes through

the ionosphere, weather conditions near the earth surface, and multipath reflections from nearby buildings and mountains. Total GPS bias error is approximately 5–10 m. Modern GPS receivers exploit doppler shift in the carrier phase of the received signals to estimate the course angle χ and the ground speed.

The accelerometers and magnetometers can be used to provide absolute attitude information on the vehicle while the rate gyroscope provides complementary angular velocity measurements. The attitude information in the magnetometer signal is straightforward to understand; in the absence of noise and bias then m_{IMU} provides a body-fixed frame measurement of $R^{\text{T}}A m$, and consequently constrains two degrees of freedom in the rotation R . The accelerometer can also be used as long as the component of acceleration associated with the inertial motion of the vehicle is compensated. The simplest way in which to do this is to use an absolute external signal such as GPS to estimate the vehicle acceleration

$$a_{\text{CTD}} = a_{\text{IMU}} - \hat{R}^{\text{T}} \ddot{\xi}_{\text{GPS}},$$

where a_{CTD} is the corrected acceleration. In this case, $a_{\text{CTD}} \approx R^{\text{T}} e_3$ and this provides attitude information. It is important to note that in the complementary filter proposed below (52.53), only the low-frequency component of a_{CTD} is required. As such, the potential noise in the second derivative of a GPS signal $\ddot{\xi}_{\text{GPS}}$ is not necessarily the problem that may be initially feared. The key to good filter performance is to ensure that the cross over frequency of the complimentary sensitivity is low enough that any phase distortion associated with low-pass filtering of $\ddot{\xi}_{\text{GPS}}$ does not effect the estimate.

Remark 52.1

There may be issues in applying the correction $\hat{R}^{\text{T}} \ddot{\xi}_{\text{GPS}}$ if there is a delay in receiving the GPS signals. This can be addressed, at the cost of storing IMU data, by combining a short time prediction along with a time-lagged observer [52.57].

In the case where GPS or an external measure of the vehicles motion is not available, there are a number of alternative techniques available to use the accelerometer information for attitude estimation. For fixed-wing vehicles, the most important disturbance is due to centripetal acceleration due to the vehicle turning. It is possible to model the centripetal acceleration using airspeed and angular velocity and compensate using a feedforward term [52.58, 59]. In the case of rotorcraft in mostly hover flight conditions, it turns out

that using the raw IMU accelerometer readings still works extremely well [52.60–62] due to the disturbance caused by the aerodynamic drag term $\Delta = -Dv$ (52.10) [52.21, 24, 25, 63]. In this case the corrected accelerometer a_{CTD} used in the filter (52.53) below is just the raw IMU accelerometer measurement.

The attitude kinematics of the quadrotor are given by (52.2c). Let \hat{R} denote an estimate for attitude R of the quadrotor vehicle. The following observer [52.61, 62] fuses accelerometer, magnetometer, and gyroscope data as well as other direct attitude estimates R_E (such as provided by a VICON or other external measurement system) should they be available

$$\dot{\hat{R}} := \hat{R} \left(\Omega_{\text{IMU}} - \hat{b} \right)_{\times} - \gamma, \quad (52.53a)$$

$$\dot{\hat{b}} := k_b \gamma, \quad (52.53b)$$

$$\begin{aligned} \gamma := & \left(\frac{k_a}{g^2} \left[(\hat{R}^{\text{T}} e_3) \times a_{\text{CTD}} \right] \right. \\ & + \frac{k_m}{A m^2} \left[(\hat{R}^{\text{T}} A m) \times m_{\text{IMU}} \right] \Big)_{\times} \\ & + k_E \mathbb{P}_{\mathfrak{so}(3)} \left(\hat{R} \hat{R}_E^{\text{T}} \right), \end{aligned} \quad (52.53c)$$

where k_a , k_m , k_E , and k_b are arbitrary nonnegative observer gains and $\mathbb{P}_{\mathfrak{so}(3)}(M) = (M - M^{\text{T}})/2$ is the Euclidean matrix projection onto the skew-symmetric matrices. If any one of the measurements in the innovation γ are not available or unreliable, then the corresponding gain should be set to zero in the observer. Note that both the attitude \hat{R} and the bias corrected angular velocity $\hat{\Omega} = \Omega_{\text{IMU}} - \hat{b}$ are estimated by this observer. The observer (52.53) has been extensively studied in the literature [52.61, 62] and shown to converge exponentially (both theoretically and experimentally) to the desired attitude estimate of attitude with \hat{b} converging to the gyroscope bias b . The filter has a complementary nature, using the high-frequency part of the gyroscope signal and the low-frequency parts of the magnetometer, accelerometer, and external attitude measurements [52.61]. The roll off frequencies associated with each of these signals is given by the gains k_a , k_m , and k_E in rad/s.

52.5.2 Estimating Velocity and Position

Estimating velocity and position is a straightforward process if the vehicle is equipped with a GPS system. In this case, the dynamics (52.2a) and (52.2b) are linear, and a linear filter can be used. Let $\hat{\xi}$ denote the estimate of position and \hat{v} denote the estimate of velocity. A sim-

ple linear filter is given by

$$\begin{aligned}\dot{\hat{\xi}} &= \hat{v} - k_x(\hat{\xi} - \xi_{\text{GPS}}), \\ \dot{\hat{v}} &= \hat{R}^T a_{\text{IMU}} - g e_3 - k_v(\hat{\xi} - \xi_{\text{GPS}}),\end{aligned}$$

for gains $k_x, k_v > 0$. As long as the attitude estimate \hat{R} is accurate, this filter design is highly robust. It is easily possible to add bias estimates for the accelerometer if desired. Equally well it is straightforward to use Kalman filter techniques to tune the gains k_x and k_v in real-time if that is considered advisable. In practice, for small aerial robotic systems, the noise characteristics of the measurements are so poor that it is often best to use a constant gain filter rather than introduce the additional complexity and potential instability of the Riccati equation associated with a Kalman filter.

In the absence of GPS, estimating position depends on the availability of additional sensor systems. Since most aerial robots are equipped with a barometer to provide an estimate of height and this can be utilized for an estimate of the vertical motion of the vehicle

$$\dot{\hat{h}} = \hat{v}_z - k_h(\hat{h} - h), \quad (52.54a)$$

$$\dot{\hat{v}}_z = e_3^T \hat{R}^T a_{\text{IMU}} - g - k_{v_z}(\hat{h} - h), \quad (52.54b)$$

where $k_h, k_{v_z} > 0$ are positive gains.

For quadrotor vehicles, there is also the possibility of exploiting the linear drag aerodynamic forces (52.10) associated with blade flapping and induced drag to estimate horizontal velocity for a vehicle in near hover conditions [52.24]. Define a projector matrix

$$\mathbb{P}_h := \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix} \quad (52.55)$$

that takes the first two components of a vector. Then the horizontal component of the *inertial* acceleration can be measured by

$${}^A a_h := \mathbb{P}_h {}^A a = \mathbb{P}_h R a \approx \mathbb{P}_h \hat{R} a, \quad (52.56)$$

where we assume that the estimate \hat{R} is close to R . If we assume the vehicle is only slowly varying in height one has $v_z \approx 0$ in comparison to horizontal velocity

$$v_h \approx \mathbb{P}_h^T v.$$

Furthermore, the thrust $T \approx mg$ must compensate the weight of the vehicle. Recalling (52.10) and taking just the horizontal component one has

$${}^A a_h \approx -g \mathbb{P}_h \hat{R} e_3 - g \mathbb{P}_h \hat{R} \hat{R}^T \mathbb{P}_h^T v_h. \quad (52.57)$$

If the attitude filter estimate is good and the assumptions about vehicle motion hold then (52.56) and (52.57) can be solved for an estimate of v_h

$$v_h \approx -\frac{1}{g} \left(\mathbb{P}_h \hat{R} \hat{R}^T \mathbb{P}_h^T \right)^{-1} \left({}^A a_h + g \mathbb{P}_h \hat{R} e_3 \right). \quad (52.58)$$

Equation (52.58) provides a measurement of the horizontal velocity, however, since it directly incorporates the unfiltered accelerometer readings it is generally too noisy to be of much use. Its low-frequency content can, however, be used to drive a velocity complementary observer that uses the attitude estimate and the system model (52.2b). Let \hat{v}_h be an estimate of the horizontal component of the inertial velocity of the vehicle then an observer is given by

$$\dot{\hat{v}}_h = -g \mathbb{P}_h^T (\hat{R} e_3 + \hat{R} \hat{D} \hat{R}^T \mathbb{P}_h^T \hat{v}_h) - k_w (\hat{v}_h - v_h), \quad (52.59)$$

where v_h is given by (52.58). The gain $k_w > 0$ provides a tuning parameters that indicates the roll-off frequency for the information from \hat{v}_h that is used in the filter. It also uses estimated velocity \hat{v}_h to provide an approximation of the more correct $\hat{R} \hat{D} \hat{R}^T \mathbb{P}_h^T v_h$ term in the feedforward velocity estimate, however, since the underlying dynamics associated with this term is stable, then the observer is stable even with this approximation. It is found that this observer works remarkably well in practice for quadrotor vehicles that are not engaged in acrobatic maneuvers [52.21, 24, 25, 63].

52.6 Conclusion

This chapter has focused on the fundamental technology associated with making an aerial robotic system operate effectively and efficiently. In particular, we have focused on the design of control and navigation algorithms, and along with that the associated questions of modeling and state estimation. Once a robust and reliable aerial robotic platform is available, the range of

potential applications for unmanned aerial systems is vast. An indication of the potential is given by a list of application categories that are already under consideration [52.64, 65]: *Remote sensing* such as pipeline spotting, power-line monitoring, volcanic sampling, mapping, meteorology, geology, and agriculture [52.66, 67], as well as unexploded mine detection [52.68].

Disaster response such as chemical sensing, flood monitoring, and wildfire management. *Surveillance* such as law enforcement, traffic monitoring, coastal and maritime patrol, and border patrols [52.69]. *Search and rescue* in low-density or hard-to-reach areas. *Transportation* including small and large cargo transport, and possibly passenger transport. *Communications* as permanent or *ad hoc* communication relays for voice

and data transmission, as well as broadcast units for television or radio. *Payload delivery* for a wide range of applications including agriculture, firefighting, and even logistics of product delivery. *Image acquisition* for cinematography and real-time entertainment. It is no surprise that aerial robotics is one of the most dynamic and exciting fields of robotics research at the moment.

53. Multiple Mobile Robot Systems

Lynne E. Parker, Daniela Rus, Gaurav S. Sukhatme

Within the context of multiple *mobile, and networked* robot systems, this chapter explores the current state of the art. After a brief introduction, we first examine architectures for multirobot cooperation, exploring the alternative approaches that have been developed. Next, we explore communications issues and their impact on multirobot teams in Sect. 53.3, followed by a discussion of networked mobile robots in Sect. 53.4. Following this we discuss swarm robot systems in Sect. 53.5 and modular robot systems in Sect. 53.6. While swarm and modular systems typically assume large numbers of homogeneous robots, other types of multirobot systems include heterogeneous robots. We therefore next discuss heterogeneity in cooperative robot teams in Sect. 53.7. Once robot teams allow for individual heterogeneity, issues of task allocation become important; Sect. 53.8 therefore discusses common approaches to task allocation. Section 53.9 discusses the challenges of multirobot learning, and some representative approaches. We outline some of the typical application domains which serve as test beds for multirobot systems research in Sect. 53.10. Finally, we conclude in Sect. 53.11 with some summary remarks and suggestions for further reading.

Researchers generally agree that multirobot systems have several advantages over single-robot systems [53.1, 2]. The most common motivations for developing multirobot system solutions are that:

1. The task complexity is too high for a single robot to accomplish.
2. The task is inherently distributed.
3. Building several resource-bounded robots is much easier than having a single powerful robot.
4. Multiple robots can solve problems faster using parallelism.
5. The introduction of multiple robots increases robustness through redundancy.

The issues that must be addressed in developing multirobot solutions are dependent upon the task requirements and the sensory and effector capabilities of the available robots.

53.1 History

Since the earliest work on multiple mobile robot systems in the 1980s, the field has grown significantly, and covers a large body of research. At the most general level, approaches to multiple mobile robot systems fall into one of two broad categories: *collective swarm* systems and *intentionally cooperative* systems. *Collective swarm* systems are those in which robots execute their own tasks with only minimal need for knowledge about other robot team members. These systems are typified by the assumption of a large number of homogeneous mobile robots, in which robots make use of local control laws to generate globally coherent team behaviors, with little explicit communication among robots. On the other hand, robots in *intentionally cooperative* systems have knowledge of the presence of other robots in the environment and act together based on the state, actions, or capabilities of their teammates in order to accomplish the same goal. Intentionally cooperative systems vary in the extent to which robots take into account the actions or state of other robots, and can lead to either strongly or weakly cooperative solutions [53.3]. *Strongly cooperative* solutions require robots to act in concert to achieve the goal, executing tasks that are not trivially serializable. Typically, these approaches require some type of communication and synchronization among the robots. *Weakly cooperative* solutions allow robots to have periods of operational independence, subsequent to coordinating their selection of tasks or roles. Intentionally cooperative multirobot systems can

The types of robots considered in the study of multiple *mobile* robot systems are those robots that move around in the environment, such as ground vehicles, aerial vehicles, or underwater vehicles. This chapter focuses specifically on the interaction of multiple *mobile* robots, as distinguished from other types of multirobot interaction. For example, a special case of multiple mobile robot systems are the *reconfigurable* or *modular* robots that interconnect with each other for the purposes of navigation or manipulation. Algorithmic aspects of these systems are covered in Sect. 53.5, while hardware aspects are covered in Chap. 22. *Networked* robotics is very closely related to multiple mobile robot systems; the focus in networked robotics is on systems of robots, sensors, embedded computers, and human users that are all connected by networked communication. Another variant of multirobot cooperation is multiple manipulator arm cooperation. Chapter 39 describes these systems in detail.

deal with heterogeneity in the robot team members, in which team members vary in their sensor and effector capabilities. In these teams, the coordination of robots can be very different from collective swarm approaches, since robots are no longer interchangeable.

Most of the work specific to multiple mobile robot cooperation can be categorized into a set of key topics of study. These topics, which are the foci of this chapter, include *architectures*, *communication*, *swarm robots*, *heterogeneity*, *task allocation*, and *learning*. *Architectures* and *communication* in multirobot systems are relevant for all types of multirobot systems, as these approaches specify how the robot team members are organized and interact. *Swarm robots* is a particular type of multirobot system, typified by large numbers of homogeneous robots that interact implicitly with each other. Such systems are often contrasted with *heterogeneous* robots, in which team members may vary significantly in their capabilities. When robots vary in capabilities, challenges arise in determining which robots should perform which tasks – a challenge commonly referred to as *task allocation*. Finally *learning* in multirobot teams is of particular interest in designing teams that are adaptive over time and can learn new behaviors. Illustrating the advances in each of these areas often takes place in a set of representative application domains; these *applications* are the final major topic of discussion in this chapter.

53.2 Architectures for Multirobot Systems

The design of the overall control architecture for the multirobot team has a significant impact on the robustness and scalability of the system. Robot architectures for multirobot teams are composed of the same fundamental components as in single-robot systems, as described in Chap. 12. However, they also must address the interaction of robots and how the group behavior will be generated from the control architectures of the individual robots in the team. Several different philosophies for multirobot team architectures are possible; the most common are *centralized*, *hierarchical*, *decentralized*, and *hybrid*.

Centralized architectures that coordinate the entire team from a single point of control are theoretically possible [53.4], although often practically unrealistic due to their vulnerability to a single point of failure, and due to the difficulty of communicating the entire system state back to the central location at a frequency suitable for real-time control. Situations in which these approaches are relevant are cases in which the centralized controller has a clear vantage point from which to observe the robots, and can easily broadcast group messages for all robots to obey [53.5].

Hierarchical architectures are realistic for some applications. In this control approach, each robot oversees the actions of a relatively small group of other robots, each of which in turn oversees yet another group of robots, and so forth, down to the lowest robot, which simply executes its part of the task. This architecture scales much better than centralized approaches, and is reminiscent of military command and control. A point of weakness for the hierarchical control architecture is recovering from failures of robots high in the control tree.

Decentralized control architectures are the most common approach for multirobot teams, and typically require robots to take actions based only on knowledge local to their situation. This control approach can be highly robust to failure, since no robot is responsible for the control of any other robot. However, achieving global coherency in these systems can be difficult, because high-level goals have to be incorporated into the local control of each robot. If the goals change, it may be difficult to revise the behavior of individual robots.

Hybrid control architectures combine local control with higher-level control approaches to achieve both robustness and the ability to influence the entire team's actions through global goals, plans, or control. Many multirobot control approaches make use of hybrid architectures.

A plethora of multirobot control architectures have been developed over the years. We focus here on three early approaches that illustrate the spectrum of control architectures. The first, the Nerd Herd, is representative of a pure *swarm* robotics approach using large numbers of homogeneous robots. The second, ALLIANCE, is representative of a behavior-based approach that enables coordination and control of possibly heterogeneous robots without explicit coordination. The third, distributed robot architecture (DIRA), is a hybrid approach that enables both robot autonomy and explicit coordination in possibly heterogeneous robot teams.

53.2.1 The Nerd Herd

One of the first studies of social behaviors in multirobot teams was conducted by Mataric [53.6], with results being demonstrated on the Nerd Herd team of 20 identical robots (shown in Fig. 53.1). This work is an example of swarm robotic systems, as described further in Sect. 53.4. The decentralized control approach was based on the subsumption architecture (Chap. 12), and assumed that all robots were homogeneous, but with relatively simple individual capabilities, such as detecting obstacles and *kin* (i.e., other robot team members). A set of basic social behaviors were defined and demonstrated, including obstacle avoidance, homing, aggregation, dispersion, following, and safe wandering. These basic behaviors were combined in various ways to yield more composite social behaviors, including flocking (composed of safe wandering, aggregation, and dispersion), surrounding (composed of safe wandering, following, and aggregation), herding (composed of safe wandering, surrounding, and flocking), and foraging (composed of safe wandering, dispersion, following, homing, and flocking). The behaviors were

Fig. 53.1 The Nerd Herd robots

implemented as rules, such as the following rule for aggregate:

```
Aggregate:
  If agent is outside aggregation
    distance
    turn toward aggregation centroid
    and go.
  Else
    stop.
```

This work showed that collective behaviors could be generated through the combination of lower-level basic behaviors. Related work on this project studied issues such as using bucket brigades to reduce interference [53.7], and learning [53.8].

53.2.2 The ALLIANCE Architecture

Another early work in multirobot team architectures is the ALLIANCE architecture (Fig. 53.2), developed by Parker [53.9] for fault-tolerant task allocation in heterogeneous robot teams. This approach builds on the subsumption architecture by adding behavior sets and motivations for achieving action selection without explicit negotiations between robots. Behavior sets group low-level behaviors together for the execution of a particular task. The motivations consist of levels of impatience and acquiescence that can raise and lower a robot's interest in activating a behavior set corresponding to a task that must be accomplished.

In this approach, the initial motivation to perform a given behavior set is set to zero. Then, at each

time step, the motivation level is recalculated based on:

1. The previous motivation level
2. The rate of impatience
3. Whether the sensory feedback indicates the behavior set is needed
4. Whether the robot has another behavior set already activated
5. Whether another robot has recently begun work on this task
6. Whether the robot is willing to give up the task, based on how long it has been attempting the task.

Effectively, the motivation continues to increase at some positive rate unless one of four situations occurs:

1. The sensory feedback indicates that the behavior set is no longer needed.
2. Another behavior set in the robot activates.
3. Some other robot has just taken over the task for the first time.
4. The robot has decided to acquiesce the task.

In any of these four situations, the motivation returns to zero. Otherwise, the motivation grows until it crosses a threshold value, at which time the behavior set is activated and the robot can be said to have selected an action. When an action is selected, cross-inhibition within that robot prevents other tasks from being activated within that same robot. When a behavior set is active in a robot, the robot broadcasts its current activity to other robots at a periodic rate.

The L-ALLIANCE extension [53.10] allows a robot to adapt the rate of change of the impatience and ac-

Fig. 53.4 The distributed robot architecture

quiescence values depending on the quality with which that robot is expected to accomplish a given task. The result is that robots that have demonstrated their ability to better accomplish certain tasks are more likely to choose those tasks in the future. Additionally, if problems occur during team performance, then robots may dynamically reallocate their tasks to compensate for the problems. This approach was demonstrated on a team of three heterogeneous robots performing a mock clean-up task, two robots performing a box-pushing task, and four robots performing a cooperative target observation problem. The approach has also been demonstrated in the simulation of a janitorial service task and a bounding overwatch task. Figure 53.3 shows robots using ALLIANCE to perform the mock clean-up task.

53.2.3 The Distributed Robot Architecture

Simmons et al. [53.11] have developed a hybrid architecture called the distributed robot architecture (DIRA). Similar to the Nerd Herd and ALLIANCE approaches, the DIRA approach allows autonomy in individual robots. However, unlike the previous approaches, DIRA also facilitates explicit coordination among robots. This approach is based on layered architectures that are popular for single-robot systems (Chap. 12). In this approach (Fig. 53.4), each robot's control architecture

Fig. 53.5 Robots using the distributed robot architecture for assembly tasks

consists of a *planning* layer that decides how to achieve high-level goals; an *executive* layer that synchronizes agents, sequences tasks, and monitors task execution; and a *behavioral* layer that interfaces to the robot's sensors and effectors. Each of these layers interacts with those above and below it. Additionally, robots can interact with each other via direct connections at each of the layers.

This architecture has been demonstrated in a team of three robots – a crane, a roving eye, and a mobile manipulator – performing a construction assembly task (Fig. 53.5). This task requires the robots to work together to connect a beam at a given location. In these demonstrations, a *foreman* agent decides which robot should move the beam at which times. Initially, the crane moves the beam to the vicinity of the emplacement based on encoder feedback. The foreman then sets up a behavioral loop between the roving eye and the crane robot to servo the beam closer to the point of emplacement. Once the beam is close enough, the foreman tasks the roving eye and the mobile manipulator to servo the arm to grasp the beam. After contact is made, the foreman tasks the roving eye and the mobile manipulator to coordinate to servo the beam to the emplacement point, thus completing the task.

53.3 Communication

A fundamental assumption in multirobot systems research is that globally coherent and efficient solutions can be achieved through the interaction of robots lacking complete global information. However, achieving these globally coherent solutions typically requires robots to obtain information about their teammates' states or actions. This information can be obtained in

a number of ways; the three most common techniques are:

1. The use of implicit communication *through the world* (called *stigmergy*), in which robots sense the effects of teammate's actions through their effects on the world [53.6, 12–16]

2. Passive action recognition, in which robots use sensors to directly observe the actions of their teammates [53.17]
3. Explicit (intentional) communication, in which robots directly and intentionally communicate relevant information through some active means, such as radio [53.9, 18–21] – an area widely studied in the field of networked robot systems.

Each of these mechanisms for exchanging information between robots has its own advantages and disadvantages [53.22]. *Stigmergy* is appealing because of its simplicity and its lack of dependence upon explicit communications channels and protocols. However, it is limited by the extent to which a robot's perception of the world reflects the salient states of the mission the robot team must accomplish. *Passive action recognition* is appealing because it does not depend upon a limited-bandwidth, fallible communication mechanism. As with implicit cooperation, however, it is limited by the degree to which a robot can successfully interpret its sensory information, as well as the difficulty of analyzing the actions of robot team members. Finally, the *explicit communication* approach is appealing because of its directness and the ease with which robots can become aware of the actions and/or goals of its teammates. The major uses of explicit communication in multirobot teams are to synchronize actions, exchange information, and to negotiate between robots. Explicit communication is a way of dealing with the *hidden-state* problem [53.23], in which limited sensors cannot distinguish between different states of the world that are important for task performance. However, explicit communication is limited in terms of fault tolerance and reliability, because it typically depends upon a noisy, limited-bandwidth communications channel that may not continually connect all members of the robot team. Thus, approaches that make use of explicit communications must also provide mechanisms to handle communication failures and lost messages.

Selecting the appropriate use of communication in a multirobot team is a design choice dependent upon the tasks to be achieved by the multirobot team. One needs to carefully consider the costs and benefits of alternative

communications approaches to determine the method that can reliably achieve the required level of system performance. Researchers generally agree that communication can have a strong positive impact on the performance of the team. One of the earliest illustrations of this impact was given in the work of *MacLennan* and *Burghardt* [53.24], which investigates the evolution of communication in simulated worlds and concludes that the communication of local robot information can result in significant performance improvements. Interestingly, for many representative applications, researchers have found a nonlinear relationship between the amount of information communicated and its impact on the performance of the team. Typically, even a small amount of information can have a significant impact on the team, as found in the study of *Balch* and *Arkin* [53.25]. However, more information does not necessarily continue to improve performance, as it can quickly overload the communications bandwidth without providing an application benefit. The challenge in multirobot systems is to discover the *optimal* pieces of information to exchange that yield these performance improvements without saturating the communications bandwidth. Currently, no general approaches to identifying this critical information are available; thus, the decision of what to communicate is an application-specific question to be answered by the system designer. *Dudek* et al.'s taxonomy of multirobot systems [53.26] includes axes related to communication, including communication range, communication topology, and communication bandwidth. These characteristics can be used to compare and contrast multirobot systems.

Several related issues of active research in communications for multirobot teams deal with dynamic network connectivity and topologies; for example, robot teams must either be able to maintain communications connectivity as they move, or employ recovery strategies that allow the robot team to recover when the communications connectivity is broken. These concerns may require robots to adapt their actions in response to the anticipated effects on the communications network, or in response to knowledge of the anticipated propagation behavior of information through the dynamic network. These and related issues are discussed next in the context of *networked robot systems*.

53.4 Networked Mobile Robots

Networked robots are multiple robots operating together coordinating and cooperating by *networked communication* to accomplish a specified task. Multiple robots enable new capabilities and the communication network enables new approaches and solutions that are

difficult with just perception and control. Communication enables new control and perception capabilities in the system (e.g., access to information outside the perception range of the robot system). Conversely, control enables solutions for problems that are difficult with-

out mobility (e.g., localization). Section 53.4.1 defines the field, examines the benefits of networking in robot coordination, and discusses applications. Section 53.4.2 highlights a few projects focused on networked robotics and discusses the application potential of the field. Section 53.4.3 discusses the research challenges at the intersection of control, communication, and perception. Section 53.4.4 defines a model for the control of a networked system which is used in Sects. 53.4.5–53.4.8 to examine specific research issues and opportunities facilitated by the interplay between communication, control, and perception.

53.4.1 Overview

The term *networked robots* refers to multiple robots operating together coordinating and cooperating by *networked communication* to accomplish a specified task. Communication between entities is fundamental to cooperation (and coordination), hence there is a central role for the communication network in networked robots. Networked robots may also involve coordination and cooperation with stationary sensors, embedded computers, and human users. The central feature of networked robots is the ability of the system to perform tasks that are well beyond the abilities of a single robot or multiple uncoordinated robots.

The IEEE (Institute of Electrical and Electronics Engineers) *Technical Committee on Networked Robots* has adopted the following definition of a networked robot:

A networked robot is a robotic device connected to a communications network such as the Internet or local-area network (LAN). The network could be wired or wireless, and based on any of a variety of protocols such as the transmission control protocol (TCP), the user datagram protocol (UDP), or 802.11. Many new applications are now being developed ranging from automation to exploration. There are two subclasses of networked robots:

1. Teleoperated, where human supervisors send commands and receive feedback via the network. Such systems support research, education, and public awareness by making valuable resources accessible to broad audiences.
2. Autonomous, where robots and sensors exchange data via the network. In such systems, the sensor network extends the effective sensing range of the robots, allowing them to communicate with each other over long distances to coordinate their activity. Sensing, actuation, and computation need no longer be collocated. A broad challenge is to develop a science base that couples communica-

tion, perception, and control to enable such new capabilities.

This definition of autonomous networked robots also includes a third class of distributed systems, mobile sensor networks, which is a natural evolution of sensor networks. Robot networks allow robots to measure spatially and temporally distributed phenomena more efficiently. The robots in turn can deploy, repair, and maintain the sensor network to increase its longevity, and utility. The focus of this chapter is *autonomous networked robots*.

Embedded computers and sensors are becoming ubiquitous in homes and factories, and increasingly wireless ad hoc networks or plug-and-play wired networks are becoming commonplace. Human users interact with embedded computers and sensors to perform tasks ranging from monitoring (e.g., supervising the operation of a factor and surveillance in a building) to control (e.g., running an assembly line consisting of sensors, actuators, and material-handling equipment). In most of these cases, the human users, embedded computers, and sensors are not collocated and the coordination and communication happens through a network. *Networked robots* extends this vision to multiple robots functioning in a wide range of environments performing tasks that require them to coordinate with other robots, cooperate with humans, and act on information derived from multiple sensors.

Figure 53.6 shows prototype concepts derived from academic laboratories and industry. In all these exam-

Fig. 53.6a–d Small modules (after [53.27]) can automatically connect and communicate information to perform locomotion tasks (a); robot arms (after [53.28]) on mobile bases can cooperate to perform household chores (b); swarms of robots (after [53.29]) can be used to explore an unknown environment (c); and industrial robots can cooperate in welding operations (d)

Fig. 53.7a–c Robotic modules (after [53.30]) can be reconfigured to morph into different locomotion systems including (a) a wheel-like rolling system, (b) a snake-like undulatory locomotion system, and (c) a four-legged walking system

ples, independent robot or robotic modules can cooperate to perform tasks that a single robot (or module) cannot perform. Robots can automatically couple to perform locomotion tasks (also Fig. 53.7) and manipulation tasks that either a single robot cannot perform, or that would require a special-purpose larger robot to perform. They can also coordinate to perform search and reconnaissance tasks exploiting the efficiency that is inherent in parallelism. They can also perform independent tasks that need to be coordinated. Examples in the manufacturing industry include, for example, fixturing and welding.

Besides being able to perform tasks that individual robots cannot perform, networked robots also result in improved efficiency. Networking gives each robot access to information outside its perception range. Tasks such as searching or mapping can, in principle, be performed faster with an increase in the number of robots. A speed up in manufacturing operations can be achieved by deploying multiple robots performing operations in parallel but in a coordinated fashion.

Another advantage of using the network to connect robots is the ability to connect and harness physically removed assets. Mobile robots can react to information sensed by other mobile robots at a remote location. Industrial robots can adapt their end-effectors to new parts being manufactured upstream in the assembly line. Human users can use machines that are remotely located via the network.

The ability to network robots also enables fault tolerance in design. If robots can dynamically reconfigure themselves using the network, they are more tolerant

to robot failures. This is seen in the Internet where multiple gateways, routers, and computers provide for a fault-tolerant system (although the Internet is not robust in other ways). Similarly, robots that can *plug* and *play* can be swapped in and out automatically to provide for a robust operating environment.

Finally, networked robots have the potential to provide great synergy by bringing together components with complementary benefits and making the whole greater than the sum of the parts.

Applications for networked robots abound. The US military routinely deploys unmanned vehicles that are reprogrammed remotely based on intelligence gathered by other unmanned vehicles, sometimes automatically. The deployment of satellites in space, often by astronauts in a shuttle with the shuttle robot arm, requires the coordination of complex instrumentation onboard the space shuttle, human operators on a ground station, the shuttle arm, and a human user on the shuttle. Home appliances now contain sensors and are becoming networked. As domestic and personal robots become more commonplace, it is natural to see these robots working with sensors and appliances in the house while cooperating with one or more human users. Networked robots will likely be used as critical ingredients in the environmental observatories of the future. Large-scale ecological monitoring precludes the use of monolithic infrastructure, and is envisioned to be built as a distributed, networked robotic system.

53.4.2 State of the Art and Potential

The growth in networked robot systems is broad-based, across many industries. There is a strong connection between this industry and the industry connected to sensor networks. Sensor networks have been projected to grow dramatically in terms of commercialization and market value [53.31]. Robot networks are analogous to sensor networks except that they allow sensors to have mobility and allow the geographical distribution of the sensors to be adapted based on the information acquired.

A system of robots, embedded computers, actuators, and sensors has tremendous potential in civilian, defense, and manufacturing applications. Nature provides the proof of concept of what is possible [53.32]. Group behaviors in nature can be found in organisms that are only microns to those that are several meters in length. There are numerous examples of simple animals that execute simple behaviors with modest sensors and actuators but communicate with and sense nearest neighbors to enable complex emergent behaviors that are fundamental to navigation, foraging, hunting, constructing nests, survival, and eventually growth. As seen

Fig. 53.8 Ants are able to cooperatively manipulate and transport objects often in large groups, without identified or labeled neighbors, and without centralized coordination

in Fig. 53.8, relatively small agents are able to manipulate objects that are significantly larger in terms of size and payload by cooperating with fairly simple individual behaviors. The coordination between agents is completely decentralized, allowing scaling up to large numbers of robots and large objects [53.33]. Individuals do not recognize each other. In other words, there is no labeling or identification of robots. The number of agents in the team is not explicitly encoded. Agents are identical, enabling robustness to failures and modularity. There is minimal communication, and even that which is present is only between neighbors. Furthermore, the optimal mode of group coordination may be scale dependent. Studies of wasps show strong evidence of centralized coordination among species with small colony sizes, but a distributed, decentralized coordination in larger colonies [53.34]. All these attributes are relevant to networked robots.

Biology has shown how simple decentralized behaviors in unidentified individuals (e.g., insects and birds exhibiting swarming behaviors) can exhibit a wide array of seemingly intelligent group behaviors. Similarly networked robots can potentially communicate and cooperate with each other, and even though individual robots may not be sophisticated, it is possible for networked robots to provide a range of intelligent behaviors that are beyond the scope of intelligent robots.

The significance and potential impact of networked robots is apparent from the following examples.

The manufacturing industry has always relied on integration between sensors, actuators, material-handling equipment, and robots. Today companies are finding it easier to reconfigure existing infrastructure by networking new robots and sensors with existing robots via wireless networks. There is also an increasing trend toward robots interacting with each other in operations like welding and machining, and robots cooperating

with humans in assembly and material-handling tasks. Workcells consist of multiple robots, numerous sensors and controllers, automated guided vehicles, and one or two human operators working in a supervisory role. However, in most of these cells, the networked robots operate in a structured environment with very little variation in configuration and/or operating conditions.

There is a growing emphasis on networking robots in applications of field robotics, for example, in the mining industry. Like the manufacturing industry, operating conditions are often unpleasant and the tasks are repetitive. However, these applications are less structured and human operators play a more important role.

In the health care industry, networks allow health care professionals to interact with their patients, other professionals, expensive diagnostic instruments, and surgical robots. Telemedicine is expected to provide a major growth impetus for remote networked robotic devices that will take the place of today's stand-alone medical devices.

There are already many commercial products, notably in Japan, where robots can be programmed via and communicate with cellular phones. For example, the MARON robot developed by Fujitsu lets a human user dial up their robot and instruct it to conduct simple tasks including sending pictures back to the user via a cellular phone. Indeed these robots will interact with other sensors and actuators in the home – door openers equipped with Bluetooth cards and actuators and computer-controlled lighting, microwaves, and dishwashers. Indeed the Network Robot Forum [53.35] is already setting standards for how stationary sensors and actuators can interact with other robots in domestic and commercial settings.

Environmental monitoring is a key application for networked robots. By exploiting mobility and communication, robotic infrastructure enables observation and data collection at unprecedented scales in various aspects of ecological monitoring. This is significant for environmental regulatory policies (e.g., clean air and water legislation), as well as an enabler of new scientific discovery. For example, it is possible to obtain maps of salinity gradients in oceans, temperature and humidity variations in forests, and chemical composition of air and water in different ecological systems [53.36]. In addition to mobile sensor networks, it is also possible to use robots to deploy sensors and to retrieve information from the sensors. Mobile platforms allow the same sensor to collect data from multiple locations while communication allows the coordinated control and aggregation of information. Examples include systems built for aquatic [53.37], terrestrial [53.38], and subsoil monitoring [53.39]. There are many efforts to develop networked underwater platforms [53.40–42].

Networks of static and robotic devices have been developed for aquatic monitoring [53.37] and to obtain high-resolution information on the spatial and temporal distributions of plankton assemblages and concomitant environmental parameters. The RiverNet project [53.43] at Rensselaer Polytechnic Institute (RPI) has focused on the development of robotic sensor networks for monitoring a river ecosystem. Recent work at University of California, Los Angeles (UCLA), University of Southern California (USC), University of California, Riverside, and University of California, Merced on the networked infomechanical system project [53.38] has focused on the development of robotic networks for monitoring the forest canopy, with a view to providing data for modeling canopy and undercover growth. Networked robotic mini-rhizotrons [53.39] are being deployed in the forest to monitor root growth in the soil.

In the defense industry, countries like the USA have invested heavily in the concept of networked, geographically distributed assets. Unmanned aerial vehicles like the Predators are operated remotely. Information from sensors on the Predators triggers the deployment of other vehicles and weapon systems at a different remote location and allows commanders in a third location to control and command all these assets. The US military engaged in the large Future Combat Systems initiative to develop network-centric approaches to deploying autonomous vehicles. The network-centric tactical paradigms for modern warfare have created networked robots for defense and homeland security. While networked robots are already in operation, current approaches are limited to human users commanding a single vehicle or sensor system. However, it takes many human operators (between 2–10 depending on the complexity of the system) to deploy complex systems like unmanned aerial vehicles. A Predator unmanned aerial vehicle (UAV) is operated from a tactical control station, which may be on an aircraft carrier, with a basic crew of 3–10 operators.

The eventual goal, however, is to enable a single human user to deploy networks of unmanned aerial, ground, surface, and underwater vehicles. There have been several recent demonstrations of multirobot systems exploring urban environments [53.44, 45] and the interiors of buildings [53.46, 47] to detect and track intruders, and transmit all of the above information to a remote operator. These examples show that it is possible to deploy networked robots using an off-the-shelf 802.11b wireless network and have the team be remotely tasked and monitored by a single operator. An example of a project with heterogeneous vehicles in an urban setting is shown in Fig. 53.9. An example of a project with heterogeneous vehicles in an indoor

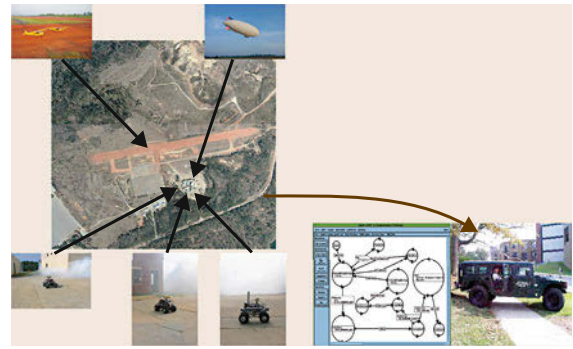

Fig. 53.9 A single operator commanding a network of aerial and ground vehicles from a command and control vehicle in an urban environment for scouting and reconnaissance in a recent demonstration by the University of Pennsylvania, Georgia Tech. and University of Southern California (after [53.48])

setting is shown in Fig. 53.10 wherein robots map an environment and deploy themselves to form a sensor network to detect intruders.

Many research projects are addressing group behaviors or collective intelligence by realizing swarming behaviors observed in nature. For example, the European Union (EU) funded several EU-wide coordinated projects on collective intelligence or swarm intelligence. The I-Swarm project in Karlsruhe [53.49] and the Swarm-Bot project at Ecole Polytechnique Fédérale de Lausanne (EPFL) [53.50] are examples of swarm intelligence. The Laboratory for Analysis and Architecture of Systems (LAAS) has a strong group in robotics and artificial intelligence. This group has had a long history of basic and applied research in multi-robot systems. The integration of multiple unmanned vehicles for applications such as terrain mapping and fire-fighting is addressed in [53.51]. A multi-university US project addressed the development of networked vehicles for swarming behaviors [53.52]. Projects such as these are exploring the scalability of the basic concepts to large numbers of robots, sensors, and actuators.

53.4.3 Research Challenges

While there are many successful embodiments of networked robots with applications to manufacturing industry, the defense industry, space exploration, domestic assistance, and civilian infrastructure, there are significant challenges that have to be overcome.

The problem of coordinating multiple autonomous units and making them cooperate creates problems at the intersection of communication, control, and perception. Who should talk to whom and what information should be conveyed, and how? How does each unit

Fig. 53.10 Under the DARPA SDR program, a team from the University of Southern California, the University of Tennessee, and Science Applications and International Corporation (SAIC) demonstrated mapping, and intruder detection by a team of networked robots (after [53.46])

move in order to accomplish the task? How should the team members acquire information? How should the team aggregate information? These are all basic questions that need basic advances in control theory, perception, and networking. In addition, because humans are part of the network (as in the case of the Internet), we have to devise an effective way for multiple humans to be embedded in the network and command/control/monitor the network without worrying about the specificity of individual robots in the network. Thus the underlying research challenges lie at the intersection of control theory, perception, and communication/networks, as shown in Fig. 53.11.

It is also worth noting that robot networks are dynamic, unlike networks of sensors, computers or machines which might be networked together in a fixed topology. When a robot moves, its neighbors change and its relationship to the environment changes. As a consequence, the information it acquires and the actions it executes must change. Not only is the network topology dynamic, but the robot's behavior also changes as the topology changes. It is very difficult to predict the performance of such dynamic robot networks, yet it is this analysis problem that designers of robot networks must solve before deploying the network.

This notion of a changing topology inevitably leads us to complicated mathematical models. Traditionally, models of group behavior have been built on continuous models of dynamics of individuals, including local interactions with neighbors, and models of control and sensing with a fixed set of neighbors. While dynamics at the level of individual units may be adequately described by differential equations, the interactions with neighbors are best described by edges on a graph. Modeling, analysis, and control of such systems will require a comprehensive theoretical framework and new representational tools. New mathematical tools that marry dynamical system theory, switched systems, discrete mathematics, graph theory, and computational geometry are needed to solve the underlying problems. We need a design methodology for solving the *inverse*

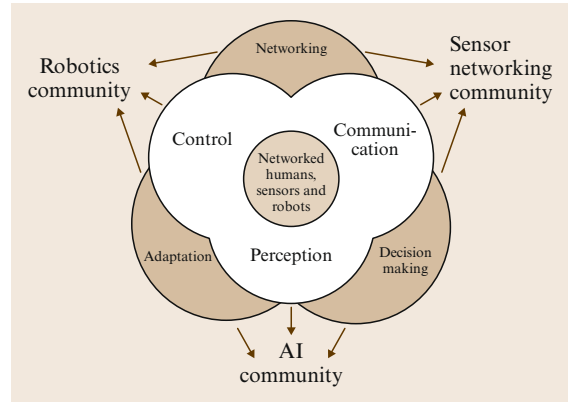

Fig. 53.11 The paradigm of *networked robots* introduces fundamental challenges at the intersection of control, perception, and communication that is of interest to the robotics, sensor networks, and artificial intelligence communities

problem in navigation – behaviors for controlling individuals to achieve a specified aggregate *motion* and *shape* of the group, and the application to active perception and coverage. An overview of some of these methods is provided in Sect. 53.4.4.

Problems of perception have been studied extensively in the robotics community. However, the perception problems in a system of networked, mobile sensor platforms bring a new set of challenges; for example, consider the problem of estimating the state of the network. State estimation requires the estimation of the state of robots and the environment based on local, limited-range sensory information. Localization of n vehicles in an m -dimensional configuration space requires $O((nm)^k)$ computations, where k is somewhere between 3 and 6, depending on the algorithm and domain-specific assumptions. The estimation problem is further exacerbated by the fact that not all robots in the network may be able to get the necessary information in a time-critical fashion. There are deep issues of representation and algorithmic development, which are discussed in Sect. 53.4.6.

The paradigm of active perception [53.53] links the control of sensor platforms to perception, bringing control theory and perception together in a common framework. Extending this paradigm to networked robots requires approaches of distributed control to be merged with decentralized estimation. Robots can move in order to localize themselves with respect to their neighbors, to localize their neighbors, and also to identify, localize, and track features in the environment. These problems are discussed in Sect. 53.4.7.

As discussed earlier, the communication network is central to the functioning of a network of robots.

However, if the network consists of mobile agents with transmitters and receivers with finite power, there is no guarantee that all agents can talk to each other. Unlike a static sensor network, robots in a network can move toward each other to facilitate communication and adaptively maintain a communication network. Some basic algorithmic problems and several pertinent results are provided in Sect. 53.4.8.

53.4.4 Control

The control of individual robots is critical to the performance and scope of robot networks. Indeed motion coordination algorithms have been proposed for the purpose of improving communication performance [53.54, 55], localization [53.56, 57], information integration, deployment [53.58], and coverage [53.59–61], among other tasks. Mobility allows the group of robots to self-deploy, and self-organize by relocating themselves in support of communication, sensing, or task needs; for example, they can reconfigure to guarantee a desired communication bandwidth, k -hop connectivity, or algebraic connectivity, enabling message delivery from one robot to another. The group can also self-organize to position sensors so as to cover a desired area and adapt to shifts in the focus of monitoring activities. Controlling sensor position also supports map making, tracking of objects and events, and goal-directed navigation for users of the network. Finally, mobility allows robots to accomplish tasks such as navigation, reconnaissance, transportation, and search and rescue.

Given a group of mobile sensors, we would like to have distributed control capabilities that realize desirable global specifications. Thus, it is necessary to be able to automatically determine the necessary position and orientation of the group members and/or the distribution of group members, and their motion to achieve the desired task. At a lower level, the robots must be able to use information from the communication network and from their own sensors to derive local estimates, reason about the spatial network (their neighbors and their relationship to the environment), and then use the appropriate control policies to achieve the desired group specifications. We briefly outline the simplest mathematical model that is necessary to formulate such problems in order to provide a better sense of the underlying challenges.

In a robot network, we have multiple agents or nodes in which each agent is a physical entity that can be a robot, a vehicle with actuators and sensors, a sensor platform (possibly static) or even a communication relay node. Each agent A_i is characterized by an identifier, $i \in I \subset \mathbb{Z}$, a state $x_i \in X_i \subset \mathbb{R}^n$, and control inputs $u_i \in U_i \subset \mathbb{R}$, with $f_i : X_i \times U_i \rightarrow TX_i$ specifying the

dynamics

$$\dot{x}_i = f_i(x_i, u_i) . \quad (53.1)$$

The state x_i will consist of the position (and orientation), r_i in some d -dimensional space, and its velocity, $\dot{r}_i : x_i = (r_i^T, \dot{r}_i^T)^T$, with $n = 2d$. $\mathcal{N}^c(r_i)$ and $\mathcal{N}^s(r_i)$ are neighborhoods of r that define the range and field of view of the communication hardware and sensors, respectively.

A network of robots S consists of N agents with a *sensing graph* and a *communications graph* that is defined by the physical distribution of the agents. The sensing graph (and similarly the communications graph) is defined by a map $E^s : X^1 \times X^2 \cdots X^N \rightarrow I \times I$, where the edges of the graph are formed dynamically depending on the physical proximity of pairs of agents. Specifically, the $N \times N$ adjacency matrix, \mathcal{A}^s (and similarly \mathcal{A}^c) has entries

$$\mathcal{A}_{ij}^s = \begin{cases} 1, & \text{if } r_j \in \mathcal{N}^s(r_i) , \\ 0, & \text{otherwise} . \end{cases} \quad (53.2)$$

Agent A_i has estimates of its own state and the states of neighbors (e.g., A_j), and these estimates are derived from information associated with edges in the sensing and communication graph

$$\hat{x}_j^{(i)} = h(x_i, z_{ij}) , \quad (53.3)$$

where z_{ij} represents measurements of the state of agent A_j available to A_i by sensing or communication channels and h is the estimator used by A_i . Note that z_{ij} may have dimension less than n and may therefore not contain complete information about $x_{ij} = x_i - x_j$. Clearly the relative position vector denoted by $r_{ij} = r_i - r_j$ and its magnitude are important quantities that may need to be estimated for biological and artificial agents.

Finally, A_i can encode n_{b_i} behaviors, which we will denote by $\mathcal{B}_i = B_1, B_2, \dots, B_{n_{b_i}}$. Each behavior B_j is a controller, a function $k_j : \mathbb{R} \times X_i \rightarrow U_i$. All agents can be assigned identical or different behaviors. Each behavior represents a set of unsynchronized, locally executed computations (for control or estimation) being carried out for some collective purpose, with each processor using in its computations only data from its *neighboring* processors. Furthermore, even for a fixed assignment of behaviors, each processor's neighbors typically *change* with time because the processors are moving in and out of the sets \mathcal{N}^c and \mathcal{N}^s . Thus the methodology for modeling and analyzing such systems will require the merging of graph theory and dynamical system theory at a fundamental level.

The reader is directed to the many survey articles on this subject for further information. An overview of challenges for the controls community is presented in [53.62]. The underlying theory for networked mobile systems has been explored in the context of automated highway systems [53.63], cooperative robot reconnaissance [53.46] and manipulation [53.64], formation flight control [53.65], and the control of groups of unmanned vehicles [53.45]. Our goal in the following sections is to explore the connections between communication, perception, and control.

53.4.5 Communication for Control

Communication networks allow physically disconnected entities to exchange information. At the lowest level, when groups of vehicles coordinate their actions, communication allows vehicles to exchange state information [53.66–68]. At a higher level, robots can plan navigation and exploration tasks based on an integrated map of the world derived from information acquired from different robots [53.52].

The use of communication for control in the multivehicle context has been addressed in the PATH project where formations of inline vehicles were studied [53.63]. Problems of the stability of the formation [53.69], the convergence of the formation to shapes [53.70], and the overall performance of the system [53.71] are of great interest. The performance of the system is directly influenced by the interconnections between agents. In addition to impacting on stability [53.63], feedback of states from different agents and feedforward information from the plans of different agents affects the rates at which the system of agents can respond to external stimuli [53.71] or to commands from human operators [53.72].

In addition, communication can be used for high-level control and planning of robots. There is great interest in using static sensor nodes as beacons to guide robot navigation. In [53.73], the problem of coverage and exploration of an unknown dynamic environment using a mobile robot is considered. An algorithm is presented which assumes that global information is not available (neither a map, nor global positioning system (GPS) information). The algorithm deploys a network of radio beacons that assists the robot in coverage. The network is also used by the robot for navigation. The deployed network can also be used for applications other than coverage (such as multirobot task allocation). A similar idea was presented using potential-field-based navigation in [53.52]. In this work the notion of no-go or danger areas was incorporated into the navigation cost function. Recent work along these lines with experimental data from sensor nodes is reported in [53.74].

In such communication-enabled cooperative control and planning (see also [53.75]), the communication network plays an important role in the creation of a shared representation of information. This notion of a shared representation is important to the scaling of coordinated control algorithms to large numbers of devices. For example, in [53.67], the information form of the Kalman filter is used to derive a framework for decentralizing estimation and fusion algorithms. This approach was shown to be applicable to multiple heterogeneous ground and aerial platforms [53.56]. Such methodologies are transparent to the specificity and identity of the cooperating vehicles. This is because vehicles share a common representation, which consists of a certainty grid that contains information about the probability of detection of targets, and an information vector–matrix pair that is used in the information form of the Kalman filter [53.45]. Observations are propagated through the network by changing both the certainty grid and the information vector/matrix. This allows each vehicle to choose the action that maximizes a utility function, which is the combined mutual information gain from onboard sensors towards the detection and localization of features in the environment.

Thus, in summary, at the lowest level, communication enables either partial or complete state feedback of the network and allows agents to exchange information for feedforward control. At the higher levels, agents can share information for planning and for control. This is also discussed in Sect. 53.4.6 where the communication network is shown to enable a network-centric approach to perception.

53.4.6 Communication for Perception

While individual robots have sensors and the ability to build maps and models by integrating sensory information, networked robots can exchange information and leverage sensory data, maps, and models from other robots. The challenge is to exploit communication for perception in tasks such as distributed mapping in the presence of the delays, limited bandwidth, and disruption that are typical of communication networks.

Distributed localization is the term used to describe the merging of communication and perception for state estimation. Localization is an essential tool for the development of low-cost robot networks for use in location-aware applications and ubiquitous networking [53.76]. Location information is needed to track the placement of the nodes and to correlate the values measured by the node with their physical location. Distributed computation and robustness in the presence of measurement noise are key ingredients for a practical

localization algorithm that will give reliable results over a large-scale network.

The methods for distributed localization can be classified into two broad classes: algorithms that rely on anchor nodes for localization and algorithms that use no beacons. Localization may be computed using range information between nodes, bearing information, or both.

In [53.54] a theoretical foundation for network localization in terms of graph rigidity theory is provided. The problem is solved when nodes have perfect range information and it is shown that a network has a unique localization if and only if its underlying graph is *generically globally rigid*. In [53.77] the Cramér–Rao lower bound (CRLB) for network localization is derived. This work computes the expected error characteristics for an ideal algorithm, and compares this to the actual error in an algorithm based on multilateration, drawing the important conclusion that the error introduced by the algorithm is just as important as the measurement error in assessing end-to-end localization accuracy. In [53.78] a distributed algorithm that uses no beacons and is guaranteed to compute correct location information under measurement noise for nodes that can range to neighbors is presented. This algorithm relies on the notion of robust quadrilaterals to compute robustly a global system of coordinates among the nodes. The computation supports moving nodes. Extensions of this work to passive tracking have been discussed in [53.79]. Localization based on the propagation of location information from known reference nodes based on connectivity includes [53.80, 81]. Mobility-assisted localization is introduced in [53.82]. Other techniques use distributed propagation of location information using multilateration [53.77, 83]. In a recent paper [53.84] the problem of evaluating the rigidity of a planar network is treated while satisfying common objectives of real-world systems: decentralization, asynchronicity, and parallelization.

Two approaches for cooperative relative localization of mobile robot teams are given in [53.85, 86]. Neither method uses GPS, landmarks, or maps of any kind; instead, robots make direct measurements of the relative pose of nearby robots and broadcast this information to the team as a whole. In [53.85], each robot processes this information independently to generate an egocentric estimate for the pose of other robots using a Bayesian formalism with a particle filter implementation. In [53.86], maximum-likelihood estimation (MLE) and numerical optimization is used to achieve a similar result.

A key issue is to be able to scale these computations for building a shared representation to large numbers of robots and sensors. This problem was studied in experiments under the US Defense Advanced Re-

search Projects Agency (DARPA-funded software for distributed robotics (SDR) program. The goal of these experiments was to develop and demonstrate a multi-robot system capable of carrying out a specific mission. This required the ability to deploy a large number of robots into an unexplored building, map the building interior, detect and track intruders, and transmit all of the above information to a remote operator. A report on one set of experiments is presented in [53.46]. A tiered strategy for deploying the robots is described, where highly capable robots formed the first wave to enter and map a building, followed by a second wave which used the resulting map to self-deploy and monitor the environment for intruders. Both approaches relied extensively on networking the robots using commercial 802.11b wireless technology. This task involved both communication for building a shared representation as well control for perception.

Another important set of problems arises when robot networks are used for identifying, localizing, and then tracking targets in a dynamic setting. An embedded stationary wireless sensor network is like a virtual sensor spread over a large geographical area. Such a network can provide information to mobile robots about remote locations. Robot networks allow this virtual sensor to move in response to external stimuli and to track moving targets. Indeed, it is possible to cast this scenario as a pursuit-evasion game with robotic sensor networks [53.87]. For example, the Tenet project at USC addresses the design of network primitives and abstractions for tiered network architectures, with robotic pursuit evasion as one of the target applications. Algorithms for guiding the sampling strategy of a robotic boat to model and locate phenomena of interest (e.g., hotspots) in aquatic environments are discussed in [53.37]. The networked infomechanical systems (NIMS) project has focused on sensor-assisted techniques for mobile robot-based adaptive sampling for event response [53.88] and field reconstruction [53.89].

The information collected by the nodes in a sensor network can be processed at a central location or in a decentralized fashion. Such in-network data processing techniques make better use of network communication and computation resources than centralized processing. This also enables the network to compute accurate and up-to-date global pictures of the global perception landscape that are available to all the robots in the system. Methods for in-network data processing with static nodes include artificial potential-field computation, gradient computations, particle filters, Bayesian inference, and signal processing. Algorithms have been developed for computing maps, paths, and predictors [53.52, 73, 90].

A recent DARPA demonstration showed how communication networks can be used effectively in perception tasks involving heterogeneous robots [53.44]. In cooperative search, identification, and localization unmanned aerial vehicles (UAVs) can be used to cover large areas, searching for targets. However, sensors on UAVs are typically limited in their accuracy of localization of targets on the ground. On the other hand, ground robots can be deployed to accurately locate ground targets but have the disadvantage of not being able to move rapidly and see through obstacles such as buildings or fences. In [53.56], the synergy between these two devices is exploited by creating a seamless network of UAVs and unmanned ground vehicles (UGVs). As discussed in Sect. 53.2, the key to such network-centric approaches for search and localization is a shared representation of state information, which in this case is easily scalable to large numbers of UAVs and UGVs and is transparent to the specificity of individual platforms. However, how to do this more generally and for more unstructured information remains an issue for future research.

53.4.7 Control for Perception

Networked mobile robots enable the exploration of dynamic environments and the recovery of three-dimensional information via distributed active perception [53.53]. Since the nodes are mobile, a natural question is: where should the nodes be placed in order to ensure successful integration of information from multiple nodes, and to maximize the quality of the estimates returned by the team? Since there is a cost associated with transmitting and processing data, it is important to consider which sensor readings should be used in the state estimation and what information should be communicated to the rest of the system. The quality of the information computed by the network depends on the locations of the sensor platforms both in an absolute and relative sense. The quality also depends on the noise characteristics of each sensor, and the communication network.

A robot network goes well beyond a fixed sensor network, which can only collect data at fixed positions in space; for example, when an event is detected at a specific location it is possible to direct more sensors toward the location of observation of the event for more information (for example, higher-resolution data or higher sampling frequency). Reconfiguring the node locations for adaptive resolution sampling relies on distributed control strategies.

Various strategies have been introduced for controlling mobile sensor network coverage. Mobile sensing agents are controlled using gradients of information-

based objective functions [53.91]. Stability results are derived without concerns for the optimality of the network configuration, but local guarantees are provided. Topology aware coordinated behavior is treated in [53.92]. A body of results reported in [53.93] and [53.94] describes decentralized control laws for positioning mobile sensor networks optimally with respect to a known event distribution density function. This approach is advantageous because it guarantees that the network (locally) minimizes a cost function relevant to the coverage problem. However, the control strategy requires that each agent have a complete knowledge of the event distribution density, thus it is not reactive to the sensed environment. The work by [53.95, 96] generalizes these results to situations in which the nodes estimate rather than know ahead of time the event distribution density function. A local (decentralized) control law requires that each agent can measure the value and gradient of the distribution density function at its own position. This results in a sensor network that is reactive to its sensed environment while maintaining or seeking a near-optimal sensing configuration. In addition, the distribution density function approximation yields a closed-form expression for the control law in terms of the vertices of an agent's Voronoi region. This eliminates the need for the numerical integration of a function over a polynomial domain at every time step, thereby providing a significant reduction in computational overhead for each agent. Other work in event monitoring for unknown distributions includes [53.59]. Krause et al. [53.97] have recently proposed an approach for sensor placement that considers both the sensing quality and communication cost of imperfect sensing and communication components. They use a parametric model for link reception rate that assumes no acknowledgement and no temporal correlation of lossy links.

Beginning with the art gallery problem, there have been multiple efforts to determine an optimal configuration of sensors to cover a given region [53.98–100]. A variant which allows the use of mobile sensors is known as the *watchmen tours* problem. In these approaches the sensor model is abstract and not well suited to real environments and cameras. Distributed geometric optimization methods [53.94] have also been used for mobile sensor network reconfiguration. A related class of methods is the use of estimation-theoretic optimization metrics and the application of information filters to coordinate network-wide motion [53.56]. There are other distributed optimization methods which use a distributed control law and show that it optimizes a global metric of interest, such as using a potential field or other linear control law based only on local neighbor interactions [53.101]. Research focusing on

the control of cameras with pan, tilt, and zoom capabilities is due to [53.60, 102, 103]. In [53.102] an approach is developed to calibrate a pan-tilt-zoom camera automatically over its full zoom range and to build very high-resolution panoramas. In [53.60], the cameras are constantly moved to track observed targets, using a factor graph. A recent algorithm due to [53.104] significantly improves on this by positioning cameras to make the network better suited to detect and classify targets as they emerge. Pan-tilt-zoom cameras allow the construction of far more flexible vision systems than static cameras.

53.4.8 Control for Communication

In Sect. 53.4.5, we briefly discussed the benefits of using the communication network to synthesize and improve controller design. Conversely, the movement of robots affects the network and data transmission in the network. This gives rise to many challenges. If the controllers for individual robots are known, can we provide guarantees about communication in the network and can we develop robust information routing and networking algorithms in the presence of robot motion? Another challenge concerns how information propagates and diffuses in these networks. If the robots move under a given control model, how does a piece of information propagate through the network and what can we say about when and where that piece of information will be heard? If we know the answers to such questions, it may be possible to design controllers to realize desired communication network characteristics.

One simple control strategy that can affect network performance is to control the robot motion to ensure messages are transmitted between designated nodes. The movement of robots in a network of robots and sensors may cause network partitioning when nodes go out of range. However, the ability of the robots to move in a controlled way also leads to an opportunity to address the information routing problem in disconnected networks by turning the robots into relay nodes. The key idea here is to enable the robot holding a current message to an unavailable destination to modify their trajectory in order to relay a message. This problem has been formulated as an optimization problem. The goal is to minimize the trajectory modifications necessary to send a message to its destination. Several solutions have been proposed depending on the information that is available to the robots. If the robots' trajectories are known, path planning techniques can be used to compute who moves where to relay what. If the robots' trajectories are not known, a distributed spanning tree can be created to enable robots to keep track of each other. Each robot is assigned a region of movement and

a parent in the spanning tree. When the robot leaves its region, the parent is informed. When the robot moves too far away, the spanning tree is modified.

Mobile robots can be used to create desired network topologies under suitable models of network communication. If a robot is used to emplace nodes in an environment (or if sensor nodes robotically self-deploy) to build a network, the problem is referred to as deployment. It is possible to control the motion of individual nodes to guarantee that a specified topology is maintained [53.55]. It is also possible to reposition nodes with the explicit aim of changing the network topology – the so-called mobility-based topology control problem.

A distributed algorithm for the deployment of mobile robot teams has been described by [53.105] using the concept of virtual pheromones: localized messages from one robot to another. These messages are used to generate either a gas expansion or a guided growth deployment model. Similar algorithms based on artificial potential fields are described in [53.106, 107], where the latter incorporates a connectivity constraint. An incremental deployment algorithm for mobile sensor networks is given in [53.58]; nodes are deployed one at a time into an unknown environment, with each node making use of information gathered by previously deployed nodes to determine its deployment location. The algorithm is designed to maximize network coverage while ensuring that nodes retain line of sight with one another.

Most work on network topology control has dealt with uncontrolled deployments, where there is no explicit control of the positions of individual nodes. The primary mechanisms proposed are power control and sleep scheduling. These methods involve pruning an already existing, well-connected communication graph in order to save power while ensuring that the resultant subgraph preserves connectivity. Given a network that is connected when all nodes are operating at maximum power, the aim of power control is to use the minimum power level at each node for which the network remains connected [53.108]. Given an overdeployed network, sleep scheduling seeks to activate a minimal subset of nodes to maintain connectivity and achieve other desired metrics [53.109]. In contrast, controlled deployments are feasible when the positions of individual nodes can be altered. Such deployments are interesting for two reasons. First, network topology with wireless communication relates directly to proximity relations and hence the position of the nodes. Second, there is increasing evidence that a large number of deployments are likely to involve careful, nonrandom placement of nodes. The positioning of nodes is controlled either by the nodes themselves or by external agents. Such net-

works present a different and interesting scenario for topology control since it is possible to exploit control of the motion and placement of the nodes to build efficient topologies. A local, completely decentralized technique for topology control using mobility is given in [53.110].

An important application for networked robots is in monitoring and surveillance, where it is important that the robots cover the space while remaining within communication range [53.111–113]. In a recent development [53.114] the problem of how to design communication models and scheduling protocols for choosing the appropriate path planning algorithms for robotic data collection is discussed. Probing environment and adaptive sleeping protocol (PEAS) was one of the first attempts to address communication connectivity and sensing coverage simultaneously using heuristic algorithms [53.115]. Wang et al. [53.116] proposed a new coverage configuration protocol (CCP) to produce an approach that simultaneously optimizes coverage and connectivity while maximizing the number of nodes that are placed into sleep mode. Furthermore, they also identified three different classes of coverage–connectivity problems with respect to the ratio of radio and sensing ranges and recognized the critical ratio

where the former range is twice as long as the latter. Zhang and Hou proved that, if the communication range is at least twice the sensing range, complete coverage of a convex area guarantees network communication connectivity, and then used this theorem as a basis for a localized density control algorithm [53.109]. This was subsequently generalized to show that the condition that the communication range is twice the sensing range is sufficient and is the tight lower bound to guarantee that complete coverage preservation implies communication connectivity among nodes if the original network topology is connected [53.117].

In summary, if the state of the communication network and the desired state of the communication network is known to each agent, it should be possible to synthesize distributed controllers to move agents to attain desired network characteristics. However, the assumptions on the global state are clearly not justified. Also, the desired motion to optimize network characteristics will conflict with the motion that is required to perform the desired task. However, as the brief discussion above illustrates, there are many interesting studies that point to promising directions for future work in this very fertile research field.

53.5 Swarm Robots

Historically, some of the earliest work in multirobot systems [53.12, 13, 118–125] dealt with large numbers of homogeneous robots, called *swarms*; swarm robotics continues to be a very active area of research. Most swarm approaches obtain inspiration from biological societies – particularly ants, bees, and birds – to develop similar behaviors in multirobot teams. Because biological societies are able to accomplish impressive group capabilities, such as the ability of termites to build large complex mounds, or the ability of ants to collectively carry large prey, robotics researchers aim to reproduce these capabilities in robot societies.

Swarm robotics systems are often called *collective* robotics, indicating that individual robots are often unaware of the actions of other robots in the system, other than information on proximity. These approaches aim to achieve a desired team-level global behavior from the interaction dynamics of individual robots following relatively simple local control laws. Swarm robotic systems typically involve very little explicit communication between robots, and instead rely on stigmergy (i.e., communication through the world) to achieve emergent cooperation. Individual robots are assumed to have minimal capabilities, with little ability to solve meaningful tasks on their own. However, when grouped with other similar robots, they are collectively able to

achieve team-level tasks. Ideally, the entire team should be able to achieve much more than individual robots working alone (i.e., it is *superadditive*, meaning that the whole is bigger than the sum of the parts). These systems assume very large numbers of robots (at least dozens, and often hundreds or thousands) and explicitly address issues of scalability. Swarm robotic approaches achieve high levels of redundancy because robots are assumed to be identical, and thus interchangeable with each other.

Many types of swarm behaviors have been studied, such as foraging, flocking, chaining, search, herding, aggregation, and containment. The majority of these swarm behaviors deal with spatially distributed multi-robot motions, requiring robots to coordinate motions either:

1. Relative to other robots
2. Relative to the environment
3. Relative to external agents
4. Relative to robots and the environment
5. Relative to all (i.e., other robots, external agents, and the environment).

Table 53.1 categorizes swarm robot behaviors according to these groupings, citing representative examples of relevant research.

Table 53.1 Categories of swarm behaviors

Relative motion requirements	Swarm behaviors
Relative to other robots	Formations [53.126, 127], flocking [53.121], natural herding (as in herds of cattle), schooling, sorting [53.14], clumping [53.14], condensation, aggregation [53.128], dispersion [53.129]
Relative to the environment	Search [53.130], foraging [53.131], grazing, harvesting, deployment [53.58], coverage [53.132], localization [53.133], mapping [53.134], exploration [53.135]
Relative to external agents	Pursuit [53.136], predator–prey [53.137], target tracking [53.138], forced herding/shepherding (as in shepherding sheep)
Relative to other robots and the environment	Containment, orbiting, surrounding, perimeter search [53.139]
Relative to other robots, external agents, and the environment	Evasion, tactical overwatch, soccer [53.140]

Much of the current research in swarm robotics is aimed at developing specific solutions to one or more of the swarm behaviors listed in Table 53.1 (👁 VIDEO 214). Some of these swarm behaviors have received particular attention, notably formations, flocking, search, coverage, and foraging. Section 53.10 discusses these behaviors in more detail. In general, most current work in the development of swarm behaviors is aimed not just at demonstrating group motions that are similar to biological systems, but also at understanding the formal control theoretic principles that can predictably converge to the desired group behaviors, and remain in stable states.

Demonstration of physical robot swarms is both a hardware and a software challenge. As discussed in Sect. 53.2, the first demonstrations were by Mataric [53.6], involving about 20 physical robots performing aggregation, dispersion, and flocking. This work defined composable *basis behaviors* as primitives for structuring more complex systems. In later research, McLurkin [53.141] (👁 VIDEO 215) developed an extensive catalog of swarm behavior software, and demonstrated these behaviors on about 100 physical robots (called the SwarmBot robots), developed by iRobot, as shown in Fig. 53.12. He created several group behaviors, such as *avoidManyRobots*, *disperseFromSource*, *disperseFromLeaves*, *disperseUniformly*, *computeAverageBearing*, *avoidManyRobots*, *followTheLeader*, *orbitGroup*, *navigateGradient*, *clusterOnSource*, and *clusterIntoGroups*. A swarm of 108 robots used the developed dispersion algorithms in an empty schoolhouse of area of about 300 m², and were able to locate an object of interest and lead a human to its location [53.129].

The European Union has sponsored many swarm robot projects, leading toward decreasingly smaller-sized individual robots, and increasingly larger-sized robot teams. The I-SWARM project, for instance, aimed at developing millimeter-sized robots with full on-board sensing, computation, and power for performing biologically inspired swarming behaviors, as well

Fig. 53.12 The SwarmBot robots

as collective perception tasks. This project was both a hardware and a software challenge, in that developing microscale robots that are fully autonomous and can perform meaningful cooperative behaviors will require significant advances in the current state of the art.

The EU-based SWARM-BOTS project studied new concepts in the design and implementation of self-organizing and self-assembling robots (👁 VIDEO 195). In this work [53.142], *s-bot* robots are developed that have grippers enabling the robots to create physical links with other s-bots or objects, thus creating assemblies of robots. These assemblies can then work together for navigation across rough terrain, or to collectively transport objects. The s-bots are cylindrical, with a flexible arm and toothed gripper that can connect one s-bot to another. An interesting application of object transport using SWARM-BOTs is shown in Figure 53.13, which shows the robots self-assembling into four chains in order to pull a child across the floor (👁 VIDEO 212).

Another notable effort in swarm robotics research is the US multi-university SWARMS initiative led by the University of Pennsylvania. Research in this project aimed at developing a new system-theoretic frame-

Fig. 53.13 SWARM-BOTs self-assembling to move a child across the floor

work for swarming, developing models of swarms and swarming behavior, analyzing swarm formation, stability, and robustness, synthesizing emergent behaviors for active perception and coverage, and developing algorithms for distributed localization.

Besides the hardware challenges of dealing with large numbers of small robots, there are many important software challenges that remain to be solved. From a practical perspective, a common approach to creating homogeneous multirobot swarms is to hypothesize a possible local control law (or laws), and then study the resulting group behavior, iterating until the desired global behavior is obtained. However, the longer-term objective is to be able to both predict group performance based on known local control laws, and to generate local control laws based upon a desired global group behavior.

More recent research has focused on the development of analytical techniques that can synthesize distributed controllers that achieve the desired macro-level system behaviors. *Mather* and *Hsieh* [53.143] address this challenge by proposing a technique that first identifies robot-robot interactions at the macroscopic level; they then use this analysis to improve local robot control policies by filtering out spurious robot-robot interactions. Another top-down design approach is presented by *Chen* et al. [53.144] who show how to automatically synthesize control and communication strategies for a robot team based on global specifications of the desired system-level behavior, stated using regular expressions. The resulting control strategies are formally proven to correctly achieve the desired global behavior. The work of *Melo* and *Veloso* [53.145] takes

a different approach to the synthesis of local decision policies by making use of the decentralized sparse-interaction Markov decision process. This technique allows agents to recognize states when interactions with other robots might occur, thus enabling them to choose better motions based on possible future inter-robot actions. *Tsiotras* and *Castro* [53.146] synthesize local controllers by generalizing the standard consensus algorithm, applied to geometric pattern formation.

A common theme in most of the works cited above is that they first make use of formal methods to describe the desired macro-level behavior, and then show how to use this macro-level goal to synthesize individual robot controllers. Another use of formal methods is to show how the individual goals of robot team members can be considered collectively, with the objective of maximizing the system's achievement of individual goals. Toward this end, game-theoretic techniques have been shown useful in a variety of distributed robot formulations. *Cheng* and *Dasgupta* [53.147] make use of the game-theoretic technique called Weighted Voting Games to address the problem of multi-robot team formation control amidst obstacles. *Taheri* et al. [53.148] also make use of game-theoretic principles, building upon the Local Interaction Game diffusion model to investigate how a small number of agents can influence the global society's behavior through local interactions.

An interesting question in the design of distributed robot coordination mechanisms is the extent to which identical controllers can lead to diversity, specialization, or changes in robot behavior. *Hsieh* et al. [53.149] study the emergence of specialization in robot swarms by making use of a distributed adaptation algorithm. They present a top-down analytical approach that defines the system equilibrium using waiting time parameters, and then present adaptive optimization strategies that converge to the optimal configurations that achieve system equilibrium. Temporal changes in system-level swarm behavior are addressed by *Hoff* et al. [53.150] who show how a swarm can change and improve its foraging behavior by switching between algorithms based on the environment in which the swarm finds itself.

Once the distributed controller is synthesized, most of the works mentioned above presume that individual robots execute their controller successfully. The typical presumption is that large swarms of interchangeable robots automatically result in robust and scalable swarm behavior. However, this presumption is challenged by *Winfield* and *Nembrini* [53.151], who illustrate that overall swarm reliability quickly falls in the presence of worst-case, partially failed robots. They conclude that future large scale swarm systems must develop new approaches for achieving high levels of fault tolerance. One example approach is shown in [VIDEO 194](#).

53.6 Modular Robotics

The modular robotics field began with a paper presented at International Conference on Robotics and Automation in the Spring of 1988 by *Fukuda and Nakagawa* [53.152] describing the abstract concept of a reconfigurable robotic system that can assume different shapes and envisioned a robot system composed of different types of modules that can combine to accomplish a variety of tasks. Over the past twenty years, modular robotics research developed many facets: hardware design; planning and control algorithms; the trade-off between hardware and algorithmic complexity; efficient simulation; and system integration.

Modular robots are collections of physically connected, electromechanically active modules that, as a whole, form robotic systems that exhibit capabilities greater than those of the individual modules. Typically modular robots can change their shape or configuration in order to adapt to a variety of different tasks. For example, a collection of modules could reconfigure from a closed chain that rolls quickly over open ground to a legged robot that more easily traverses rough terrain. Modular robots are typically touted for their adaptability, their fault-tolerance, and the relative simplicity of the unit modules. Modular robotic systems can be described and classified on several axes using a variety of properties. In what follows, we choose the traditional route of classifying modular robotic systems by the geometry of the system: chain, lattice, truss, or free form. For a more detailed history of the modular robotics field, consult [53.153, 154].

53.6.1 Chain Systems

The defining characteristic of chain-type modular robot systems is the fact that the modules, when connected to their neighbors, are arranged in a chain. These chains may be one-dimensional, or two-dimensional, but three-dimensional chains are not as common. The fact that a chain-type modular robot is two-dimensional, or even one-dimensional, does not mean that it cannot operate in three dimensions. In fact, snake-like modular robots composed of segments with orthogonal joints are quite common.

One of the first chain-type modular robotic systems was the polypod system developed by *Yim* [53.155, 156] ( VIDEO 196). The polypod system was composed of two types of modules: segments and nodes. It could form a variety of shapes including rolling loops and hexapods, and it went on to inspire many other chain-based systems. One was the CONRO system [53.157–159] in which each module was composed of two orthogonal servo motors controlling each module's pitch and yaw.

Murata et al. developed the M-TRAN modular robotic system [53.160–163] which has undergone multiple revisions and improvements. In [53.161], Kamimura et al. employ a set of interconnected, out of phase oscillators to achieve walking gaits in the M-TRAN system. *Marbach* and *Ijspeert* improved upon the ability of systems like M-TRAN to generate gaits in real-time by applying function optimization to their modular system, YaMoR [53.164]. *Murata* et al. added cameras to the M-TRAN system so that a set of M-TRAN modules could separate, perform independent tasks, and then rejoin into a larger structure [53.163].

The ATRON system [53.165, 166] was developed to improve upon the M-TRAN. Lund et al. wanted to keep M-TRAN's ability to form dense lattices while taking advantage of the two orthogonal degrees of freedom, (pitch and yaw), found in the CONRO system. The Superbot system [53.167] also builds upon on the mechanical design of M-TRAN by adding an additional degree of rotational freedom between the two existing rotation axes.

The PolyBot is chain-type modular robot [53.168, 169] with a single rotational degree of freedom. PolyBot evolved into CKBot which has demonstrated the ability to reassemble itself after being accidentally or intentionally destroyed [53.170]. The Molecube system [53.171], developed by *Lipson* et al. is another example of a chain-type modular system with only one degree of freedom but still able to achieve interesting three-dimensional (3-D) configurations. Lipson et al. showed that a short chain of Molecube modules, along with some free modules, can self-replicate.

Yim et al. designed another unique chain-type system named RATChET [53.172] which uses a connected chain of inter-latching right angle tetrahedrons to form structures. Neighboring RATChET modules latch together when the angle between them passes some critical value, and they unlatch through the use of shape memory alloy (SMA) springs when heated beyond 70 °C. Interestingly, the RATChET modules possess no intelligence. Instead, they rely on an intelligent external actuator which rotates to control one end of the dangling chain. One unique property of the RATChET system is its relatively strength.

53.6.2 Lattice Systems

Lattice-type modular robot systems are collections of interconnected robotic modules in which the units are situated at the intersection points of a two or three dimensional grid. (A 1-D (one-dimensional) lattice system is simply a chain-type robot.) The main characteris-

tic separating a lattice system from a densely configured chain-type robot is the density of the interconnections between the modules. In a lattice-type system, each module is typically connected to all of its neighbors. In a dense chain-type system, two modules may be neighbors, but they will not be physically connected.

Additionally, lattice-type systems tend to be built with modules that contain no rotational degrees of freedom. While the modules in a lattice system typically have mechanisms which enable the modules to move relative to, and bond with, their neighbors, they generally cannot bend themselves. In comparison, chain-type systems are often built from modules that contain one or more rotational degrees of free so that the modules can flex like links in a chain. There is some overlap between the two types of system.

Chirikjian et al. developed one of the first lattice-based modular robotic systems [53.173–175] (📺 VIDEO 198) in which the modules are deformable hexagons capable of bonding with their neighbors. Others, such as *Walter* et al. [53.176] further analyzed these hexagonal type systems to create distributed motion planners capable of reconfiguring the system from one state to another.

Murata et al. were also early contributors to the development of lattice-based modular robotic systems with their development of a roughly hexagonal module capable of rolling around its neighbors in two dimensions [53.177, 178]. *Kurokawa* et al. presented a three dimensional adaptation [53.179] composed of cubes with six protruding arms capable of rotation. *Yoshida* et al. improved on this system with a new design that used shape-memory alloy actuators to rotate one robot module around the perimeter of a neighbor [53.180].

One of the simplest lattice systems is the Digital Clay project [53.181]. The system was a set of completely passive modules that relied on the user to make changes to its topology. The 2.5 cm rhombic dodecahedrons were able to sense and communicate with their neighbors in order to create a virtual model of the physical arrangement of modules.

Rus et al. also explored the idea of 3-D modules capable reconfiguration through a series of latching, rotations, and unlatching with the Molecule system [53.182–185]. In [53.186, 187], *Vona* and *Rus* describe a different type of deformable lattice system. The Crystal system is composed of square modules able to expand and contract by a factor of two in the x - y plane. *Suh* et al. expanded on the Crystal concept with the Telecubes [53.188] that could move in three dimensions by expanding all six faces.

Chiang and *Chirikjian* analyzed how to perform motion planning in a lattice of rigid cubic modules able to slide past each other [53.189]. The CHOBIE

robot developed by *Koseki* [53.190] is able to actually perform the sliding motion assumed by *Chiang* and *Chirikjian* in [53.189]. More recently, *An* developed the EM-Cube system [53.191] which is also capable of sliding motion.

Another unique lattice is the I-Cube developed by *Khosla* et al. [53.192, 193]. The 3-D I-Cube system consists of passive cubes which are connected by active links with three rotational degrees of freedom that are able to grab, reposition, and release the cubes. The 3-D I-Cube system was an improvement of the two-dimensional (2-D) system [53.194] developed by *Hosokawa* et al. for rearranging cubic modules in a vertical plane.

Goldstein et al. initiated the Claytronics project by publishing several papers [53.195, 196] proposing lattice-based *claytronic atoms* or catoms. These vertically-oriented cylindrical robots, which were incapable of independent motion, used 24 electromagnets around their perimeters to achieve rolling locomotion about their neighbors. Goldstein et al. envisioned a system in which millions of smaller catoms could form arbitrary shapes using a randomized algorithm that avoided conveying a complete description of the shape to each module in the system.

The catoms continue to evolve. One of the newest instantiations [53.197] employs hollow cylinders rolled from SiO₂ rectangles patterned with aluminum electrodes. The authors hope that two of these cylinders, when placed in close proximity with their axes aligned, will be able to rotate with respect to one another using electrostatic forces. Specifically, the electrodes, (which reside on the inside of each cylinder and are electrically isolated by the SiO₂), will be charged so that they attract and repel mirror charges on the neighboring cylinder in a way that causes rotation. Currently, the system appears to be constrained to form 2-D structures. The authors claim the completed system will have a yield strength similar to that of plastic and that the modules will be able to transfer power and communication signals capacitively from neighbor to neighbor.

The Claytronics project has proposed, but not yet demonstrated with hardware, the use of sub-millimeter intelligent particles as sensing and replication devices [53.198]. In particular, *Pillai* et al. present a theoretical 3-D fax machine in which the object to be faxed is immersed in a container of intelligent particles that sense and encode the object's dimensions. At the receiving end, these same Claytronic particles decode the shape description sent by the transmitter and bond together to replicate the original object. Unlike our approach, *Pillai's* approach is completely centralized and relies on an external computer for computation.

White et al. developed hardware and algorithms for several 2-D stochastically-driven self-assembling sys-

tems [53.199]. To form specific shapes, each module is provided with a representation of the desired shape and decides, based on its location in the structure, whether to allow other modules to bond to its faces. *Lipson* et al. extended their 2-D system to 3-D [53.200–202] by using cubic modules suspended in turbulent fluid to achieve self-assembly and reconfiguration. As the free modules circulate in the fluid, they pass by a growing structure of assembled modules. When they come close enough, they are accreted onto the structure. The modules attract or repel each other with fluid suction or positive pressure. Early versions of the system used modules with interval values that could redirect these suction forces. More recently, *Lipson*'s group has worked to move the intelligence and actuation capabilities from the modules to the tank in which the modules circulate [53.203].

The Mische system [53.204] consisting of 45 mm cubic modules capable of mating with their neighbors using mechanically switchable permanent magnets. Each module contains three switchable magnets, each of which mated with a steel face on a neighboring module. Because the connectors were gendered, any collection of modules had to be assembled by hand so that the connectors were always oriented correctly, but the system was capable of self-disassembling to form 3-D structures. The Robot Pebbles (VIDEO 211) are based, at least in principle, on the Mische modules.

One of the newest lattice-type modular robotics is an aerial system composed of identical, hexagonal, single-rotor modules [53.205]. A group of modules may connect to form a flying platform with an arbitrary arrangement of multiple rotors. In addition to the ability to fly, each module contains wheels so that the system may self-reconfigure on the ground for the specific task at hand.

53.6.3 Truss Systems

Truss systems, as their name implies, are modular robotic systems in which the modules are nodes and edges in a truss structure. Both the trusses and connectors may be active in such systems. Unlike the lattice-based systems, truss-based systems do not need to operate on any regular lattice. Most truss-based systems under development employ struts that expand or contract to achieve structural deformation. One of the first such system to do so was Tetrobot [53.206]. The Odin system, conceived by *Lyder* et al. [53.207, 208] consists of three physically different types of modules: active strut modules capable of changing their length; passive strut modules of fixed length; and joint modules. The biologically inspired Morpho system [53.209] developed by *Nagpal* et al. is similar to Odin. It also uses active links, passive links, and connector cubes.

53.6.4 Free-Form Systems

Free-form systems are able to aggregate modules in at least semi-arbitrary positions. One such system is the Slimebot [53.210, 211]. The system consists of identical vertical cylindrical modules that move on a horizontal plane. The perimeter of each module is covered by six gender-less hook and loop patches used to bond with neighboring modules. These patches oscillate radially in and out from the center of the body. By controlling the frequency and phase of the oscillations between neighbors, the system can achieve aggregate motion in a given direction.

Researchers are also developing algorithms for free-form systems. *Funiak* et al. developed a localization algorithm [53.212] that is capable of localizing tens-of-thousands of irregularly packed modules in 3-D. *Rubenstein* and *Shen* developed a number of shape formation algorithms for collections of two-dimensional modules. These algorithms allow an arbitrary-sized collection of modules to form arbitrary scale-independent shapes [53.213, 214]. Once the shape is formed, modules can be added to or removed from the system, and the system will reconfigure itself to incorporate the new modules. The resulting shape will grow or shrink, but its basic form will remain unchanged. Recently, *Rubenstein* et al. developed a 1000 modules hardware platform on which to deploy these algorithms [53.215].

Researchers have also explored the use of folding to create reconfigurable foldable systems [53.216, 217]. These systems use flexible wiring and shape memory alloy actuators embedded in composite sheets to programmatically create origami-inspired shapes. By controlling which actuators are energized, the system can form multiple different shapes.

53.6.5 Self-Assembling Systems

Self-assembling modular robotic systems are collection of modules that are capable of autonomously coalescing and bonding with their neighbors to form a greater structure. The result is often robotic, but it need not be. Whether a system is capable of self-assembling is independent of whether it is free-form, a chain, a lattice, or a truss-based system. Almost all of aforementioned modular robot systems rely on human intervention to assemble. In an attempt to automate the process of creating intricate modular robotic systems, researchers have attempted to mimic and improve upon natural self-assembling systems. *Whitesides* et al. investigated a wide variety of engineered self-assembling systems [53.218–220].

Miyashita et al. performed a more theoretical analysis of self-assembly using pie-shaped pieces

to form complete circles [53.221] from pie-shaped pieces. In the process, they followed *Hosokawa et al.*'s lead [53.222] and modeled the system as a chemical reaction. *Shimizu* and *Suzuki* developed a system of passive modules capable of self-repair when placed on a vibrating table [53.223].

Computer scientists have also investigated theoretical aspects of self-assembly in the context of 2-D tiles which selectively bond with their neighbors to form simple well-defined shapes like squares [53.224–226]. Each side of every tile in the system has an associated bonding strength. When two tiles collide, they remain attached only if their cumulative bond strength exceeds a globally defined system entropy. To form a specific shape, one must design a set of tiles with the appropriate bonding strengths.

Klavins et al. worked to develop intelligent self-assembling systems that employ triangular modules driven by oscillating fans on an air table to self-assemble different shapes [53.227]. The authors employ knowledge of the module's local topology and internal module state so that each module decides, in a distributed fashion, when to maintain or break a connection with its immediate neighbors. *Griffith et al.* also worked with intelligent modules capable of selective bonding to show that self-assembling systems may self-replicate [53.228].

Rus et al. [53.185] present the first generic rule-based approach to self-assembly, shape formation, and locomotion by reconfiguration. The rules can be used on any modular robot system that can implement the sliding cube model of relative motion. The result is an abstract set of rules for each of these tasks, that can be compiled down to module motions, taking into account how the physical module implements translation and convex and concave transitions.

Jones and Mataric [53.229] presented rule-based approach to self-assembly termed transition rule sets. In particular, they present a method that, given a goal structure, produces a set of rules shared among all modules that govern when and where new modules are allowed to attach to the growing structure. *Kelly and Zhang* [53.230] expanded on this work by optimizing the size of the rule sets used to form a specific shape.

Werfel [53.231] also applied the idea of a transition rule set when studying the use of swarms to assemble complex structures from passive materials.

Other groups have attempted to make self-assembly more deterministic. The MEMS (micro-electromechanical system) robots developed by *Donald et al.* [53.232, 233] consists of thin (7–20 μm), rectangular ($\approx 260 \mu\text{m} \times 60 \mu\text{m}$), scratch-drive devices capable of moving on an insulating substrate embedded with electrodes. The authors used four of these robots to build larger composite structures. The *Sitti* group has developed a similar system of micro-meter sized robots [53.234]. Instead of using a scratch drive for locomotion, the robots are manipulated by external magnetic fields. The authors can electrostatically clamp any number of robots to the stage on which they move. With all but one robot immobilized, the remaining robot may be moved independently. The system naturally self-assembles because the robots contain permanent magnets that attract their neighbors.

The majority of existing self-assembly systems aim to form structures in one of two ways. Some systems such as [53.221, 223–226] use a collection of application specific differentiated modules, that are only capable of assembling in a particular fashion to form a specific shape. In contrast, other systems such as [53.199–201, 227, 229–231, 235] use completely generic modules with more computation and communication ability embedded in each module. Both types of systems aim to form complex shapes in a direct manner: as these structures grow from a single module, new modules are only allowed to attach to the structure in specific locations.

An alternative approach eliminates many of the complexities of shape formation by active assembly by using disassembly for shape formation. The *Smart Pebble* system [53.154, 204, 236, 237] employs a set of distributed algorithms to perform two discrete steps: 1) rely on stochastic forces to self-assemble a close-packed crystalline lattice of modules and 2) use the process of self-disassembly to remove the extra material from this block leaving behind the goal structure. By approaching shape formation in this manner, the entire shape-formation process is sped-up and the robustness of the system is increased.

53.7 Heterogeneity

Robot heterogeneity can be defined in terms of variety in robot behavior, morphology, performance quality, size, and cognition. In most large-scale multirobot systems work, the benefits of parallelism, redundancy, and solutions distributed in space and time are obtained

through the use of homogeneous robots, which are completely interchangeable (i. e., the swarm approach, as described in Sect. 53.4). However, certain complex applications of large-scale robot teams may require the simultaneous use of multiple types of sensors and

robots, all of which cannot be designed into a single type of robot. Some robots may need to be scaled to smaller sizes, which will limit their payloads, or certain required sensors may be too expensive to duplicate across all robots on the team. Other robots may need to be large to carry application-specific payload or sensors, or to navigate long distances in a limited time. These applications, therefore, require the collaboration of large numbers of heterogeneous robots.

The motivation for developing heterogeneity in multirobot teams is thus twofold: heterogeneity may be a design feature beneficial to particular applications, or heterogeneity may be a necessity. As a design feature, heterogeneity can offer economic benefits, since it can be easier to distribute varying capabilities across multiple team members rather than to build many copies of monolithic robots. Heterogeneity can also offer engineering benefits, as it may simply be too difficult to design individual robots that incorporate all of the sensing, computational, and effector requirements of a given application. Heterogeneity in behavior may also arise in an emergent manner in physically homogeneous teams, as a result of behavior specialization.

A second compelling reason to study heterogeneity is that it may be a necessity, in that it is nearly impossible in practice to build a truly homogeneous robot team. The realities of individual robot design, construction, and experience will inevitably cause a multirobot system to drift to heterogeneity over time. This is recognized by experienced roboticists, who have seen that several copies of the same model of robot can vary widely in capabilities due to differences in sensor tuning, calibration, etc. Over time, even minor initial differences among robots will grow due to individual robot drift and wear and tear. The implication is that, to employ robot teams effectively, we must understand diversity, predict how it will impact performance, and enable robots to adapt to the diverse capabilities of their peers. In fact, it is often advantageous to build diversity explicitly into the design of a robot team.

There are a variety of research challenges in heterogeneous multirobot systems. A particular challenge to achieving efficient autonomous control is when overlap in team member capabilities occurs, thus affecting task allocation or role assignments [53.238]. Techniques as described in Sect. 53.6 can typically deal with heterogeneous robots for the purposes of task allocation. Another important topic in heterogeneity is how to recognize and quantify heterogeneity in multirobot teams. Some types of heterogeneity can be evaluated quantitatively, using metrics such as the social entropy metric developed by Balch [53.239]. Most research in heterogeneous multirobot systems assumes that robots have a common language and a common understanding of

symbols in their language; developing a common understanding of communicated symbols among robots with different physical capabilities is a fundamental challenge, addressed by Jung and Zelinsky [53.240] (👁️ VIDEO 200).

As discussed in Sect. 53.2, one of the earliest research demonstrations of heterogeneity in physical robot teams was in the development of the ALLIANCE architecture by Parker [53.9]. This work demonstrated the ability of robots to compensate for heterogeneity in team members during task allocation and execution. Murphy has studied heterogeneity in the context of marsupial robot deployment, where a *mothership* robot assists smaller robots in applications such as search and rescue [53.241] (👁️ VIDEO 206). Grabowski et al. [53.134] developed modular millibots for surveillance and reconnaissance that could be composed of interchangeable sensor and effector components, thus creating a variety of different heterogeneous teams. Simmons et al. [53.11] demonstrated the use of heterogeneous robots for autonomous assembly and construction tasks relevant to space applications. Sukhatme et al. [53.242] demonstrated a helicopter robot cooperating with two ground robots in tasks involving marsupial-inspired payload deployment and recovery, cooperative localization, and reconnaissance and surveillance tasks, as shown in Fig. 53.14. Parker et al. [53.243] demonstrated assistive navigation for sensor network deployment using a more intelligent leader robot for guiding navigationally challenged simple sensor robots to goal locations, as part of a larger demonstration by Howard et al. [53.244] of 100 robots performing exploration, mapping, deployment, and detection. Chaimowicz et al. [53.245] demonstrated a team of aerial and ground robots cooperating for surveillance applications in urban environments. Parker and Tang [53.246] developed ASyMTRe (automated

Fig. 53.14 Heterogeneous team of an air and two ground vehicles that can perform cooperative reconnaissance and surveillance

synthesis of multirobot task solutions through software reconfiguration), which enables heterogeneous robots to share sensory resources to enable the team to accomplish tasks that would be impossible without tightly coupled sensor sharing.

Many open research issues remain to be solved in heterogeneous multirobot teams; for example, the issue of optimal team design is a very challenging problem. Clearly, the required behavioral performance in a given

application dictates certain constraints on the physical design of the robot team members. However, it is also clear that multiple choices may be made in designing a solution to a given application, based upon cost, robot availability, ease of software design, flexibility in robot use, and so forth. Designing an optimal robot team for a given application requires significant analysis and consideration of the tradeoffs in alternative strategies.

53.8 Task Allocation

In many multirobot applications, the mission of the team is defined as a set of tasks that must be completed. Each task can usually be worked on by a variety of different robots; conversely, each robot can usually work on a variety of different tasks. In many applications, a task is decomposed into independent subtasks [53.9], hierarchical task trees [53.247], or roles [53.11, 245, 248, 249] either by a general autonomous planner or by the human designer. Independent subtasks or roles can be achieved concurrently, while subtasks in task trees are achieved according to their interdependence. Once the set of tasks or subtasks have been identified, the challenge is to determine the preferred mapping of robots to tasks (or subtasks). This is the *task allocation* problem.

The details of the task allocation problem can vary in many dimensions, such as the number of robots required per task, the number of tasks a robot can work on at a time, the coordination dependencies among tasks, and the time frame for which task assignments are determined. Gerkey and Mataric [53.250] defined a taxonomy for task allocation that provides a way of distinguishing task allocation problems along these dimensions, which is referred to as the multirobot task allocation (MRTA) taxonomy.

53.8.1 Taxonomy for Task Allocation

Generally, tasks are considered to be of two principal types: *single-robot tasks* (SR, according to the MRTA taxonomy) are those that require only one robot at a time, while *multirobot tasks* (MR) are those that require more than one robot working on the same task at the same time. Commonly, single-robot tasks that have minimal task interdependencies are referred to as *loosely coupled tasks*, representing a *weakly cooperative* solution. On the other hand, multirobot tasks are often considered to be sets of subtasks that have strong interdependencies. These tasks are therefore often referred to as *tightly coupled tasks* that require a *strongly cooperative* solution. The subtasks of a loosely coupled multirobot task require a high level of synchroniza-

tion or coordination between subtasks, meaning that each task must be aware of the current state of the coordinated subtasks within a small time delay. As this time delay becomes progressively larger, coordinated subtasks become more loosely coupled, representing weakly cooperative solutions.

Robots can also be categorized as either *single-task robots* (ST), which work on only one task at a time or *multitask robots* (MT), which are able to make progress on more than one task at a time. Most commonly, task allocation problems assume robots are single-task robots, since more capable robots that perform multiple tasks in parallel are still beyond the current state of the art.

Tasks can either be assigned to optimize the instantaneous allocation of tasks (IA), or to optimize the assignments into the future (TA, for time-extended assignment). In the case of instantaneous assignment, no consideration is made for the effect of the current assignment on future assignments. Time-extended assignments attempt to assign tasks so that the performance of the team is optimized for the entire set of tasks that may be required, not just the current set of tasks that need to be achieved at the current time step.

Using the MRTA taxonomy, triples of these abbreviations are used to categorize various task allocation approaches, such as SR-ST-IA, which refers to an assignment problem in which single-robot tasks are assigned once to single-task robots. Different variations of the task allocation problem have different computational complexities. The easiest variant is the ST-SR-IA problem, which can be solved in polynomial time since it is an instance of the optimal assignment problem [53.251]. Other variants are much more difficult, and do not have known polynomial time solutions. For example, the ST-MR-IA variant can be shown to be an instance of the set partitioning problem [53.252], which is strongly NP-hard. The ST-MR-TA, MT-SR-IA, and MT-SR-TA variants have also all been shown to be NP-hard problems. Because these problems are computationally complex, most approaches to task allocation in multirobot teams generate approximate solutions.

53.8.2 Representative Approaches

Approaches to task allocation in multirobot teams can be roughly divided into behavior-based approaches and market-based (sometimes called negotiation-style or auction-based) approaches. The following subsections describe some representative architectures for each of these general approaches. Refer to [53.250] for a comparative analysis of some of these approaches, in terms of computation and communications requirements and solution quality.

Behavior-Based Task Allocation

Behavior-based approaches typically enable robots to determine task assignments without explicitly discussing individual tasks. In these approaches, robots use knowledge of the current state of the robot team mission, robot team member capabilities, and robot actions to decide, in a distributed fashion, which robot should perform which task.

One of the earliest architectures for multirobot task allocation that was demonstrated on physical robots was the behavior-based ALLIANCE architecture [53.9] and the related L-ALLIANCE architecture [53.10]. ALLIANCE addresses the **ST-SR-IA** and **ST-SR-TA** variants of the task allocation problem without explicit communication among robots about tasks. As described in Sect. 53.2.2, ALLIANCE achieves adaptive action selection through the use of motivational behaviors, which are levels of impatience and acquiescence within each robot that determine its own and its teammates' relative fitness for performing certain tasks. These motivations are calculated based upon the mission requirements, the activities and capabilities of teammates, and the robots' internal states. These motivations effectively calculate utility measures for each robot–task pair.

Another behavior-based approach to multirobot task allocation is broadcast of local eligibility (**BLE**) [53.253], which addresses the **ST-SR-IA** variant of task allocation. **BLE** uses a subsumption style behavior control architecture [53.254] that allows robots to efficiently execute tasks by continuously broadcasting locally computed eligibilities and only selecting the robot with the best eligibility to perform the task. In this case, task allocation is achieved through behavior inhibition. **BLE** uses an assignment algorithm that is very similar to *Botelho* and *Alami*'s **M+** architecture [53.255].

Market-Based Task Allocation

Market-based (or negotiation-based) approaches typically involve explicit communications between robots about the required tasks, in which robots bid for tasks

based on their capabilities and availability. The negotiation process is based on market theory, in which the team seeks to optimize an objective function based upon individual robot utilities for performing particular tasks. The approaches typically greedily assign subtasks to the robot that can perform the task with the highest utility.

Smith's contract net protocol (**CNP**) [53.256] was the first to address the problem of how agents can negotiate to collectively solve a set of tasks. The use of a market-based approach specifically for multirobot task allocation was first developed by *Botelho* and *Alami* with their **M+** architecture [53.255]. In the **M+** approach, robots plan their own individual plans for the task they have been assigned. They then negotiate with other teammates to incrementally adapt their actions to suit the team as a whole, through the use of social rules that facilitate the merging of plans.

Since these early developments, many alternative approaches to market-based task allocation have been developed. A thorough survey on the current state of the art in market-based techniques for multirobot task allocation is given in [53.257], comparing alternative approaches in terms of solution quality, scalability, dynamic events and environments, and heterogeneous teams.

Most of the current approaches in market-based task allocation address the **ST-SR** problem variant, with some approaches (e.g., [53.11, 258–260]) dealing with instantaneous assignment (**IA**), and others (e.g., [53.135, 261–263]) addressing time-extended assignments (**TA**). More recent methods are beginning to address the coalition formation problem, which is the allocation of multirobot tasks (i.e., the **MR-ST** problem variant), including [53.246, 264–269]. An example approach to the **MR-MT** problem variant is found in [53.270].

Some representative market-based techniques include **MURDOCH** [53.258], **TraderBots** [53.247, 263], and **Hoplites** [53.265]. The **MURDOCH** approach [53.258] employs a resource-centric, publish–subscribe communication model to carry out auctions, which has the advantage of anonymous communication. In this approach a task is represented by the required resources, such as the environmental sensors. The methods for how to use such a sensor to generate satisfactory results is preprogrammed into the robot.

The **TraderBots** approach [53.247, 263] applies market economy techniques for generating efficient and robust multirobot coordination in dynamic environments. In a market economy, robots act based on selfish interests. A robot receives revenue and incurs cost when trying to accomplish a task. The goal is for robots to

trade tasks through auctions/negotiations such that the team profit (revenue minus cost) is optimized.

The Hoplites approach [53.265] focuses on the selection of an appropriate joint plan for the team to execute by incorporating joint revenue and cost into the bid. This approach couples planning with passive and active coordination strategies, enabling robots to change coordination strategies as the needs of the task

change. Strategies are predefined for a robot to accomplish a selected plan.

Some alternative approaches formulate the objects to be assigned as *roles*, which typically package a set of tasks and/or behaviors that a robot should undertake when acting in a particular role. Roles can then be dynamically assigned to robots in a similar manner as in the auction-based approaches [53.11, 248].

53.9 Learning

Multirobot learning is the problem of learning new cooperative behaviors, or learning in the presence of other robots. The other robots in the environment, however, have their own goals and may be learning in parallel [53.271]. The challenge is that having other robots in the environment violates the Markov property that is a fundamental assumption of single-robot learning approaches [53.271]. The multirobot learning problem is particularly challenging because it combines the difficulties of single-robot learning with multiagent learning. Particular difficulties that must be considered in multirobot learning include continuous state and action spaces, exponential state spaces, distributed credit assignment, limited training time and insufficient training data, uncertainty in sensing and shared information, nondeterministic actions, difficulty in defining appropriate abstractions for learned information, and difficulty of merging information learned from different robot experiences.

The types of applications that have been studied for multirobot learning include multitarget observation [53.272, 273], air fleet control [53.274], predator-prey [53.137, 275, 276], box pushing [53.277], foraging [53.23], and multirobot soccer [53.140, 278]. Particularly challenging domains for multirobot learning are those tasks that are *inherently* cooperative. Inherently cooperative tasks are those that cannot be decomposed into independent subtasks to be solved by individual robots. Instead, the utility of the action of one robot is dependent upon the current actions of the other team members. This type of task is a particular challenge in multirobot learning, due to the difficulty of assigning credit for the individual actions of the robot team members.

The credit assignment problem is a particular challenge, since it is difficult for a robot to determine whether the fitness (either good or bad) is due to its own actions, or due to the actions of another robot. As discussed by Pugh and Martinoli in [53.279], this problem can be especially difficult in situations where robots do

not explicitly share their intentions. Two different variations of the credit assignment problem are common in multirobot learning. The first is when robots are learning individual behaviors in the presence of other robots that can affect their performance. The second is when robots are attempting to learn a task with a shared fitness function. It can be difficult to determine how to decompose the fitness function to appropriately reward or penalize the contributions of individual robots.

While learning has been explored extensively in the area of single-robot systems (see, for example, the discussion of learning in behavior-based systems in Chap. 13, and a discussion of fundamental learning techniques in Chap. 15) and in multiagent systems [53.280], much less work has been done in the area of multirobot learning, although the topic is gaining increased interest. Much of the work to date has focused on reinforcement learning approaches. Some examples of this multirobot learning research include the work by Asada et al. [53.281], who propose a method for learning new behaviors by coordinating previously learned behaviors using Q-learning, and apply it to soccer-playing robots. Mataric [53.8] introduces a method for combining basic behaviors into higher-level behaviors through the use of unsupervised reinforcement learning, heterogeneous reward functions, and progress estimators. This mechanism was applied to a team of robots learning to perform a foraging task. Kubo and Kakazu [53.282] proposed another reinforcement learning mechanism that uses a progress value for determining reinforcement, and applied it to simulated ant colonies competing for food. Fernandez and Parker [53.272] apply a reinforcement learning algorithm that combines supervised function approximation with generalization methods based on state-space discretization, and apply it to robots learning the multi-object tracking problem. Bowling and Veloso [53.271] developed a general-purpose, scalable learning algorithm called GraWoLF (gradient-based win or learn fast), which combines gradient-based policy learning

techniques with a variable learning rate, and demonstrated the results in the adversarial multirobot soccer application.

Other multirobot learning approaches not based on reinforcement include *Parker's* L-ALLIANCE architecture [53.10], which uses parameter tuning, based on

statistical experience data, to learn the fitness of different heterogeneous robots in performing a set of tasks. *Pugh* and *Martinoli* [53.279] apply particle swarm optimization techniques to distributed unsupervised robot learning in groups, for the task of learning obstacle avoidance.

53.10 Applications

Many real-world applications can potentially benefit from the use of multiple mobile robot systems. Example applications include container management in ports [53.283], extraplanetary exploration [53.284], search and rescue [53.241], mineral mining, transportation, industrial and household maintenance, construction [53.11], hazardous waste cleanup [53.9], security [53.285, 286], agriculture, and warehouse management [53.287] ( VIDEO 210). Multiple robot systems are also used in the domain of localization, mapping, and exploration; Chap. 46 mentions some of the work in multirobot systems applied to these problems. Parts F and G of this handbook outline many application areas that are relevant not only to single-robot systems, but also to multiple mobile robot systems. To date, relatively few real-world implementations of these multirobot systems have occurred, primarily due to the complexities of multiple robot systems and the relative newness of the supporting technologies. Nevertheless, many proof-of-principle demonstrations of physical multirobot systems have been achieved, and the expectation is that these systems will find their way into practical implementations as the technology continues to mature.

Research in multiple mobile robot systems is often explored in the context of common application test domains. While not yet elevated to the level of benchmark tasks, these common domains do provide opportunities for researchers to compare and contrast alternative strategies to multirobot control. Additionally, even though these common test domains are usually just laboratory experiments, they do have relevance to real-world applications. This section outlines these common application domains; see also [53.2] and [53.288] for a discussion of these domains and a more detailed listing of related research.

53.10.1 Foraging and Coverage

Foraging is a popular testing application for multirobot systems, particularly for those approaches that address swarm robotics, involving very large numbers of mobile robots. In the foraging domain, objects such as pucks

or simulated food pellets are distributed across the planar terrain, and robots are tasked with collecting the objects and delivering them to one or more gathering locations, such as a home base. Foraging lends itself to the study of weakly cooperative robot systems, in that the actions of individual robots do not have to be tightly synchronized with each other. This task has traditionally been of interest in multirobot systems because of its close analogy to the biological systems that motivate swarm robotics research. However, it also has relevance to several real-world applications, such as toxic waste cleanup, search and rescue, and demining. Additionally, since foraging usually requires robots to completely explore their terrain in order to discover the objects of interest, the *coverage* domain has similar issues to the foraging application. In coverage, robots are required to visit all areas of their environment, perhaps searching for objects (such as landmines) or executing some action in all parts of the environment (e.g., for floor cleaning). The coverage application also has real-world relevance to tasks such as demining, lawn care, environmental mapping, and agriculture.

In foraging and coverage applications, a fundamental question is how to enable the robots to explore their environments quickly without duplicating actions or interfering with each other. Alternative strategies can include basic stigmergy [53.14], forming chains [53.120], and making use of heterogeneous robots [53.131]. Other research demonstrated in the foraging and/or coverage domain includes [53.23, 132, 289–294].

53.10.2 Flocking and Formations

Coordinating the motions of robots relative to each other has been a topic of interest in multiple mobile robot systems since the inception of the field. In particular, much attention has been paid to the flocking and formation control problems ( VIDEO 217,  VIDEO 293). The flocking problem could be viewed as a subcase of the formation control problem, requiring robots to move together along some path in the aggregate, but with only minimal requirements for paths taken by specific robots. Formations are stricter, requiring robots to

maintain certain relative positions as they move through the environment. In these problems, robots are assumed to have only minimal sensing, computation, effector, and communications capabilities. A key question in both flocking and formation control research is determining the design of local control laws for each robot that generate the desired emergent collective behavior. Other issues include how robots cooperatively localize themselves to achieve formation control [53.133, 295], and how paths can be planned for permutation-invariant multirobot formations [53.296].

Early solutions to the flocking problem in artificial agents were generated by *Reynolds* [53.297] using a rule-based approach. Similar behavior- or rule-based approaches have been used physical robot demonstrations and studies, such as in [53.121, 298]. These earlier solutions were based on human-generated local control rules that were demonstrated to work in practice. More recent work is based on control theoretic principles, with a focus on proving stability and convergence properties in multirobot team behaviors. Examples of this work include [53.128, 299–307]. Refer to [53.308, 309] for surveys of relevant control theoretic work.

53.10.3 Object Transportation and Cooperative Manipulation

Some of the earliest work in swarm robotics was aimed at the object transportation task [53.13, 123, 310–313], which requires a team of robots to move an object from its current position in the environment to some goal destination (📺 VIDEO 193). The primary benefit of using collective robots for this task is that the individual robots can combine forces to move objects that are too heavy for individual robots working alone or in small teams. However, the task is not without its challenges; it is non-trivial to design decentralized robot control algorithms that can effectively coordinate robot team members during object transportation. A further complication is that the interaction dynamics of the robots with the object can be sensitive to certain object geometries [53.314, 315] and object rotations during transportation [53.315], thus exacerbating the control problem.

Object transportation and cooperative manipulation are popular domains for demonstrating multirobot cooperation, because they offer a clear domain where close coordination and cooperation is required. A common type of object transportation – box pushing – requires robot teams to move boxes from their starting positions to defined goal configurations, sometimes along specified paths. Typically, box pushing operates in the plane, and the assumption is made that the boxes are too heavy or too long to enable single robots to

push alone. Sometimes there are several boxes to be moved, with ordering dependencies constraining the sequence of motions. Cooperative manipulation is similar, except it requires robots to lift and carry objects to a destination. This test bed domain lends itself to the study of strongly cooperative multirobot strategies, since robots often have to synchronize their actions to successfully execute these tasks. The domain of box pushing and cooperative manipulation is also popular because it has relevance to several real-world applications [53.288], including warehouse stocking, truck loading and unloading, transporting large objects in industrial environments, and assembly of large-scale structures.

Researchers usually emphasize different aspects of their cooperative control approach in the box pushing and cooperative manipulation domain. For example, *Kube and Zhang* [53.13] (📺 VIDEO 199) demonstrate how swarm-type cooperative control techniques could achieve box pushing (Fig. 53.15), *Parker* [53.10, 316] illustrates aspects of adaptive task allocation and learning, *Donald et al.* [53.317] (📺 VIDEO 208) illustrates concepts of information invariance and the interchangeability of sensing, communication, and control, and *Simmons et al.* [53.11] demonstrate the feasibility of cooperative control for building planetary habitats.

In general, the manipulation techniques used for collective object transportation can be grouped into three primary methods [53.318]: pushing, grasping, and caging. The pushing approach [53.10, 11, 13, 316, 317] requires contact between each robot and the object, in order to impart force in the goal direction; however, the robots are not physically connected with the object. In the grasping approach [53.123, 142, 310–312, 319–322], each robot in the team physically attaches to the object being transported. See for example Fig. 53.16

Fig. 53.15 Collective pushing of lighted box

Fig. 53.16 Cooperative stick pulling

Fig. 53.17 Collective transport via caging

for cooperative stick pulling work of [53.320]. Finally, the caging approach [53.323–326] (👁️ VIDEO 292) involves robots encircling the object so that the object moves in the desired direction, even without the constant contact of all the robots with the object. See Fig. 53.17 for an example of collective transport via caging, from [53.323].

A closely related task is that of collective construction and wall building. The objective of the collective construction and wall building task is for robots to build structures of a specified form, in either 2-D or 3-D. This task is distinguished from self-reconfigurable robots, whose bodies themselves serve as the dynamic structure. Werfel and Nagpal have extensively explored this topic (👁️ VIDEO 216), developing distributed algorithms that enable simplified robots to build structures based on provided blueprints, both in 2-D [53.327–329] and in 3-D [53.330]. In their 3-D approach, the system consists of idealized mobile robots that perform the construction, and smart blocks that serve as the passive structure. The robots' job is to provide the mobility, while the blocks' role is to identify places in the growing structure at which an additional block can be placed that is on the path toward obtaining the desired final

structure. The goal of their work is to be able to deploy some number of robots and free blocks into a construction zone, along with a single block that serves as a seed for the structure, and then have the construction to proceed autonomously according to the provided blueprint of the desired structure.

Hardware challenges of collective robot construction are addressed by Terada and Murata [53.331]. In this work, a hardware design is proposed that defines passive building blocks, along with an assembler robot that constructs structures with the robots. Other related work on the topic of collective construction includes the work of Wawerla et al. [53.332], in which robots use a behavior-based approach to build a linear wall using blocks equipped with either positive or negative Velcro, distinguished by block color. Their results show that adding 1 bit of state information to communicate the color of the last attached block provides a significant improvement in the collective performance. The work by Stewart and Russell [53.333, 334] proposes a distributed approach to building a loose wall structure with a robot swarm.

Another type of construction is called blind bulldozing, which is inspired by a behavior observed in certain ant colonies. Rather than constructing by accumulating materials, this approach achieves construction by removing materials. This task has practical application in site clearing, such as would be needed for planetary exploration [53.335]. Early ideas of this concept were discussed by Brooks et al. in [53.336], which argues for large numbers of small robots to be delivered to the lunar surface for site preparation. Parker et al. [53.337], further develop this idea by proposing robots using force sensors to clear an area by pushing material to the edges of the work site.

A significant body of additional research has been illustrated in this domain; representative examples include [53.3, 6, 123, 258, 284, 310, 323, 338–344].

53.10.4 Multitarget Observation

The domain of multitarget observation requires multiple robots to monitor and/or observe multiple targets moving through the environment. The objective is to maximize the amount of time, or the likelihood, that the targets remain in view by some team member throughout task execution. The task can be especially challenging if there are more targets than robots. This application domain can be useful for studying strongly cooperative task solutions, since robots have to coordinate their motions or the switching of targets to follow in order to maximize their objective. In the context of multiple mobile robot applications, the planar version of this test bed was first introduced

in [53.345] as cooperative multirobot observation of multiple moving targets (CMOMMT). Similar problems have been studied by several researchers, and extended to more complex problems such as environments with complex topography or three-dimensional versions for multiple aerial vehicle applications. This domain is also related to problems in other areas, such as art gallery algorithms, pursuit evasion, and sensor coverage. This domain has practical application in many security, surveillance, and reconnaissance problems. Research applied to the multitarget observation problem in multirobot systems includes [53.138, 253, 346–353].

53.10.5 Traffic Control and Multirobot Path Planning

When multiple robots are operating in a shared environment, they must coordinate their actions to prevent interference. These problems typically arise when the space in which robots operate contains bottlenecks, such as networks of roadways, or when the robots take up a relatively large portion of the navigable space. In these problems, the open space can be viewed as a resource that robots must share as efficiently as possible, avoiding collisions and deadlocks. In this domain, robots usually have their own individual goals, and must work with other robots to ensure that they receive use of the shared space to the extent needed to achieve their goals. In some variants, the entire paths of multiple robots need to be coordinated with each other; in other variants, robots must simply avoid interfering with each other.

A variety of techniques have been introduced to address this problem, including traffic rules, subdividing the environment into single-ownership sections, and geometric path planning ([53.354] for an overview). Many of the earliest research approaches to this problem were based on heuristic approaches, such as predefining motion control (or traffic) rules that were shown to prevent deadlock [53.355–358], or using techniques similar to mutual exclusion in distributed computing [53.359, 360]. These approaches have the benefit of minimizing the planning cost for obtaining a solution. Other, more formal, techniques view the application as a geometric multirobot path planning problem that can be solved precisely in configuration space–time. Chapter 7 includes a discussion of motion planning for multiple robots relevant to this domain. While geometric motion planning approaches provide the most general solutions, they can often be too computationally intensive for practical application, impractical due to the dynamic nature of the environment, or simply unnecessary

Fig. 53.18 Legged robot teams competing in robot soccer

for the problem at hand. In these cases, approximation approaches may be sufficient, such as centralized techniques that limit the search space through roadmapping [53.361, 362], and decoupled approaches that use either prioritized planning [53.363–365] (i.e., generating robot paths one by one) or path coordination (i.e., first planning individual paths for robots, then handling collision avoidance).

53.10.6 Soccer

Since the inception of the RoboCup multirobot soccer domain as a proposed challenge problem for studying coordination and control in multirobot systems [53.366], research in this domain has grown tremendously. This domain incorporates many challenging aspects of multirobot control, including collaboration, robot control architectures, strategy acquisition, real-time reasoning and action, sensor fusion, dealing with adversarial environments, cognitive modeling, and learning. Annual competitions show the ever-improving team capabilities of the robots in a variety of settings, as shown in Fig. 53.18. A key aspect of this domain that is not present in the other multirobot test domains is that robots must operate in *adversarial* environments. This domain is also popular because of its educational benefits, as it brings together students and researchers from across the world in competitions to win the RoboCup challenges. The RoboCup competitions have added an additional search-and-rescue category to the competition [53.367], which has also become a significant area of research (Chap. 66 for more details on this field). Annual proceedings of the RoboCup competitions document much of the research that is incorporated into the multirobot soccer teams. Some representative research works include [53.368–372] (VIDEO 202, VIDEO 209).

53.11 Conclusions and Further Reading

This chapter has surveyed the current state of the art in multirobot systems, examining architectures, communications issues, swarm robot systems, heterogeneous teams, task allocation, learning, and applications. Clearly, significant advances have been made in the field in the last decade. The field is still an active area of research, however, since many open research issues still remain to be solved. Key open research questions remain in the broad areas of system integration, robustness, learning, scalability, generalization, and dealing with heterogeneity.

For example, in the area of system *integration*, an open question is how to effectively allow robot teams to combine a spectrum of approaches toward achieving complete systems that can perform more than a limited set of tasks. We are a long way from creating robust robot networks that can perform physical tasks in the real world. In the area of *robustness*, multi-robot teams still need improvements in the ability to degrade gracefully, to reason for fault tolerance, and to achieve complexity without escalating failure rates. The area of *learning* in multirobot teams is still in its infancy, with open questions including how to achieve continual learning in multirobot teams, how to facilitate the use of complex representations, and how to enable humans to influence and/or understand the results of the team learning. *Scalability* is still a challenging problem, in terms of more complex environments as well as ever-larger numbers of robots. We do not yet have a methodology for creating self-organizing robot networks that are robust to labeling (or numbering), with completely decentralized controllers and estimators, and with provable emergent response. This

requires basic research at the intersection of control, perception, and communication. Open issues in *generalization* include enabling the robot team to reason about context and increasing the versatility of systems so that they can operate in a variety of different applications. In dealing with *heterogeneity*, open questions include determining theoretical approaches to predicting system performance when all robots are not equal, and determining how to design a robot team optimally for a given application. Advances over the last decade have provided human users with the ability to interact with hundreds or thousands of computers on the Internet. It is necessary to develop similar network-centric approaches to interfacing, both for control and for monitoring. Finally, a major challenge is to create systems that are proactive and anticipate our needs and commands rather than reacting (with delays) to human commands.

For further reading on the topic of multiple mobile robot systems, the reader is referred to survey articles in the field, including [53.2, 288, 373, 374]. Additionally, several special journal issues on this topic have appeared, including [53.1, 375–377]. Some taxonomies of multirobot systems are given in [53.26, 288, 378]. A variety of symposia and workshops have been held on a regular basis on the topic of multirobot systems, in particular the **DARS** (distributed autonomous robotic systems) series of symposia. Recent proceedings of these workshops and symposia include [53.379–388]. Additional texts on this topic include [53.389–391]. For some excellent further background on networked robotics we direct the reader to [53.31, 35, 46, 52, 55, 75, 90, 104].
